21578 Mountsfield Drive
Golden, CO 80401
(303) 526-1626
Telex: 4943345 RANDOL

NOTE

This report is based on information provided by literally hundreds of individuals in mining, engineering, and consulting companies. The author gratefully acknowledges this industry support without which RANDOL surveys would not be possible.

The information contained herein is submitted on a "best efforts" basis. Although an attempt has been made to avoid misleading errors, this report should be used by sponsors at their own risk and subject to verification. Since it deals with a pioneering field, it has not been altogether possible to avoid speculative assessments.

Some of the information may possibly be "sensitive." This report is submitted to you on condition that sponsors hold its contents strictly confidential.

TRIP REPORTS AND OPERATION DESCRIPTIONS

VOLUME 1

WATER MANAGEMENT & TREATMENT IN MINING & METALLURGICAL OPERATIONS

Table of Contents

Conversion Factors

Introduction 1

- The Need for Information on Water Management/Treatment 2
- Objectives of this Report 5
- The Systems Approach 6
- Defining the Problem 8
- The Challenge 9
- The Opportunity 11
- The Snag 11
- The Approach 12
- Guiding Rules 12

CHAPTER 1 - INFLUENCE OF MINING AND MINERAL PROCESSING ON WATER QUALITY AND THE ENVIRONMENT 15

Introduction 17

Ways in which mining can affect the environment: 18

- Acid Mine Drainage 19
  - Illustrations of Acid Mine Drainage Examples 21
  - The Witwatersrand 27
  - Elliot Lake Uranium Tailings 33
  - Base Metal and Gold Mines-Canadian Shield and B.C. 35
  - Coal Mining 38
  - Gold and Base Metals, Colorado 39
  - Mine Drainage: Nevada 42
  - Abandoned Base Metal Mines: California 43
    Sulfur Bank Mine, Walker Mine, and The Penn Mine 43
  - Wisconsin: Shullsburg District 44
- Reagents Used in Mineral Processing 44
- Metallurgical Process Solution Effluents 47
  - Hydrometallurgy 47
  - Flotation 47
  - Pyrometallurgical Processes 48
  - Effluents 49
- Organics and Petrochemicals 49

Suspended Solids 50
Temperature 52
Some technologies that reduce water contamination: 52
Mining Methods and Backfill Technology 52
Tailings Disposal Technology 53
Tailings Retreatment 55
Impoundment Technology 55
Water Treatment 56
Water Management Advances 56
Conclusions 56
References 58

CHAPTER 2 - OBJECTIVES AND SCOPE OF WATER MANAGEMENT 61

What is a Systems Approach? 62
How to Apply a Systems Approach 63
Water Management and Metallurgical Engineering 64
The Real Cost of Water 65
Honeymoon Project, Australia 67
A Canadian Uranium Mill - No Systems Approach 68
Systems Approach: Selecting a Water Treatment Process 68
The Overall Water Cost for Two Gold Recovery Operations 69
Scope of Water Management 69
References 71
Resources Conservation Co. - Brochure on Water Management 73

CHAPTER 3 - REVIEW OF WATER USE, AVAILABILITY, AND COST AT MINES AND MILLS 75

- Use of Water in Mines and Mills 79
- Annual Cost of Water for Mine-Mill Operations 80
- Annual Cost of "New" Water Intake at Mine-Mill Operations 81
- Summary: Water Consumption in Mineral Processing 83
- Survey of Water in Gold-Silver Recovery Operations 89

CHAPTER 4 - REVIEW OF WATER PROBLEMS IN MINES AND MILLS 103

- Mine Dewatering - Operating and Abandoned Mines 103
- Tailings and Wasterock Runoff and Seepage 110
- Quality of Available Water Supply: 112

- Purchased Water 112
- River Water 112
- Ground Water 113
- Recycled Sewage Water 114
- Tailings Return Water 116

° Water Problems in Mines: 117
- Cooling and Ventilation 117
- Underground Sludges 119
- Disinfection 122
- Scale Formation 126
- Corrosion 128

° Water Problems in Mineral Processing and Extractive Metallurgy 136
° Mill Tailings Disposal 137
° Reagent Storage and Spills 140
° Boiler Water 141
° Potable and Service Water for Mines and Mills 141
° Disposal of Contaminants 141

CHAPTER 5 - WATER RECYCLING IN METALLURGICAL PLANTS 143

Conclusions 143
How Water is Recycled 144
Examples of Water Recycling in Flowsheets 145
Percent Recycle vs. Net Water Consumption 146
Incentive for Recycling 146
Examples of Water Recycling 147
- Rössing Uranium Ltd. 147
- New Mexico Uranium Operations 152

Macro Recycle and Effects 152
In-Situ Leach 153
Water Recycling in Base Metal Flotation Plants 153
Examples 153
Fluorspar Flotation 162
Lead Copper Separation Using Hexavalent Chromium 162
Gold and Silver Heap Leaching 163
Counter-Current Heap Leaching 165
Vat Leaching, Australia 166
Cyanide Soluble Base Metals 166
Carbon Adsorption vs. Merrill-Crowe and Water Recycling 167
Economics of Water Recycling 161
Problems Arising from Water Recycling 172
References 172

CHAPTER 6 - SUMMARY OF WATER QUALITY STANDARDS 175

Destruction Between Effluent Permits and Objectives 176
CIRCLA - Superthreat 177
Base Metal Refineries and Smelter Effluent Rules - U.S.A. 177
Summary Table of Water quality Standards 179
South African Effluent Standards 185
Brazil 187
Sweden 188

CHAPTER 7 - SUMMARY OF CRITICAL REGULATIONS GOVERNING EFFLUENTS 189a

Introduction 189
U.S.A. 190
Critical Regulations U.S.A. 193
Solid Waste Program 195
U.S. Acts of Congress-Federal Law 195
Bills Before Congress 198
U.S. Federal Regulations 198
Notes on Regulation and Licensing in California 200
Noranda Grey Eagle: California Regional Water Quality Control Board, Order 205
McLaughlin Mine: California Regional Water Quality Control Board, NPDES Permit for Waste Discharge 228
Copy of Discharge Specifications for ASARCO Waterloo Project, California 233
CANADA 235
SOUTH AFRICA 236
South African Regulations 237
New Regulations and Pending Changes 239
Conclusions - South Africa 240
Inplications of Amendments to the Water Act, S.A. Mining and Engineering Journal, November, 1984. 243
BRAZIL 247
CHILE 251
Decree Number 86 of July 31, 1970, Regulations for the Construction and Operation of Tailings Ponds 251
SWEDEN 259

- Witwatersrand Gold-Uranium Concept 366
- Copper-Lead-Zinc Flotation 367
- Belt Press Water Recovery from Tailings 368
- References 368

CHAPTER 12 - REMOVAL OF SUSPENDED SOLIDS 369

Motivation 370
Technology Goals 370
Technologies 370
° Coagulation and Flocculation 371
What is Coagulation, and What is Flocculation 372
Coagulation 372
Zeta Potential 373
Coagulation and Flocculation Chemicals 374
Activated Silica 376
Coagulant Aids 376
Flocculation 377
° Flocculation in Placer Mining 377
° Coagulants and Flocculants in Mineral Processing 378

- Nature of Precipitates 380
- Clarifiers 381
  - Lamella Clarifiers 381
  - Cylindrical Clarifiers 403
  - Cylindrical Conical Settlers 405
  - Hopper Clarifier 405
- Dispersed and Dissolved Air Flotation 407
  - DAF-Rexnord Envirex Division 408
  - Tricellerator DAF for Low Density AMD Precipitate Removal 411
  - Bluebird Mine, SX Reagent Recovery 413
  - Precipitate Flotation of Iron Cyanide Complexes 419
  - DAF - General 420
- Electroflotation of Precipitates 421
- Settling and Polishing Ponds 422
  - Onaping Mine 422
  - Biological Systems 425
  - Multi-Media and Deep-Bed Filters 427
  - AMAX, Mount Emmons 427
  - Dynasand Filter 428
  - Mixed Media Technology - Neptune Microfloc 435
  - Application and Results of Deep-Bed Filtration by John A. Buchanan 439
- Cross-Flow Filtration and Ultra Filtration 443
  - Removal of Trace Elements and Acidity from the ARGO Mine Tunnel Drainage - J. DAVID HOLM and DONALD H. SIMPSON (1981) Excerpt 445
- Hydroperm Cross Flow Microfiltration - COMSTOCK, et al. (1983) 447
- Reverse Osmosis (Seeded Slurry R.O.) 470
- Magnetic Filters 471
- Coarse Particle Separation 472
  - Filtomat Brochure 473
- References 486

CHAPTER 13 - REMOVAL OF DISSOLVED SOLIDS 489

Motivation 489
Technologies 490
  - Precipitation 490
  - Calcium and Bicarbonate Solubility vs. pH 492
  - Desalination 494
  - Reverse Osmosis 502
  - Electrodialysis (ED) and Electrodialysis Reversal (EDR) 504

Desalination: South African Perspective - Chapter 11 - Economic Considerations, C. F. SCHUTTE (1983) 505
Evaporation 518
Ion Exchange 520
Freezing 521
Comparison of Desalination Processes 522
Disposal of Concentrates 522
References 524

CHAPTER 14 - PRECIPITATION PROCESSES 527

Principles 527
Applicability 528
Oxidation of Iron 529
Equilibration 529
Lime Addition Processes 529
High Density Sludge Process 533
Cominco Ltd.'s Effluent Treatment Plant at Its Trail, B.C. Metallurgical Operation. R. H. WATSON and J. D. TURNBULL (1983) 535
Magnesium Carbonate Treatment Process 538
Magnesium Oxide Process 538
Limestone Addition Processes 539
NaOH Addition 539
Chemical Interference with Precipitation 541
H_2S Polishing of Solutions 542
Use of Plants to Polish Effluents 544
Densification and Disposal of Precipitated Sludges 545
References 546

WATER MANAGEMENT & TREATMENT IN MINING & METALLURGICAL OPERATIONS

CHAPTER 25 - REMOVAL OF CONTAMINANTS 1699

Standard Treatments - Summary 1700
Six Cardinal Rules 1701
"Other" Treatment and Polishing Processes: 1701
- Recovery of Values by Selective Precipitation 1702
- Recovery of Values by IX: 1703
  - Quivira Mining, Ambrosia Lake, New Mexico 1704
  - U_3O_8 Recovery, Cotter Corp., Golden, Colorado 1704
  - U_3O_8 Recovery, Denison Mines Ltd. 1705
  - Copper Recovery, Elteniente Minewater, Peru 1705
  - Copper Recovery, Centromin, Peru 1706
  - Molybdenum Recovery, Climax, Colorado 1706
  - Metal Removal by IX - Examples 1707
  - Desalination Using CIX 1708
  - Sirotherm 1709
- Sulfide Precipitation 1712
- Insoluble Starch/Cellulose Xanthate 1714
- Two-Stage Process Chemically Treats Mine Drainage to Remove Dissolved Metals by H. Peter Larsen and Laurence W. Ross 1715
- Characterization of Boliden's Sulfide-Lime Precipitation System, Blythe, et al. (1981) 1719

INTRODUCTION

This investigation has been both frustrating and rewarding. Rewarding because of new insights into some of the many creative possible approaches to water management and their implications for metallurgical operations. Water quality has an impact on metallurgical processes. Some water treatment processes may be integrated into the mine-mill system as metallurgical tools.

The frustrating part has been the often poor quality of available information and understanding of many aspects which are clearly important in optimized mining and metal recovery operations. Another frustrating aspect has been the unwillingness or inability of several companies to cooperate by providing information of interest for this survey. Industry support of this investigation has been disappointing and it has had to be subsidized by RANDOL INTERNATIONAL LTD. to the tune of around $100,000. Sponsors of this study include companies that seem to be the most knowledgable about water management and treatment, and one has to assume that many of the rest do not yet appreciate its significance.

This report is disappointing in that it has not found all the answers that it set out to find. It nonetheless documents the results of two years' intense effort which is more than was promised and should, therefore, be a useful frame of reference or departure point for further work.

It is certainly true that the mining industry, especially in North America, is going through a tough time economically. In fact, in the U.S.A. today, it must be recognized that the industry is still in a depression with retrenchments and mine closures being a common occurrence. It is therefore perhaps not surprising that some mining companies would not now welcome information on new or improved technologies for water treatment or even new water management practices. The installation of new water treatment facilities, however good they may be, means spending money, and right now the mining industry needs to conserve all the cash it can in its effort to stay afloat. Even changing a plant around to implement a new or changed water management plan requires an investment.

Then, there is the struggle with some regulatory agencies who sometimes make seemingly unreasonable demands for expensive water treatment technologies which may put a value on a trout's life at thousands of dollars. The way the regulatory framework in the U.S.A. has developed in this respect is currently counterproductive as will be shown in this report. A point has been reached that when a U.S. mining company does develop an innovative new water treatment process, it is likely to instinctively hide it away so that regulatory agencies do not hear of it. The fear is that if regulators find an improved technology, then they will force all mining and milling operations to use it too. On the other hand, if a U.S. mining company installs a new water treatment process and it fails

to meet the expected performance, then the company will, more likely than not, try to downplay its failure. Even if the regulatory authorities are accommodating, there is always the risk that some private environmental group may learn of the failure. As entitled by present U.S. law, they may demand information from the regulators' files and may also file suit for damages where they find that permit requirements have or are not being met. Consequently, mining companies do not freely admit that a promising process or item of equipment installed to treat water fails to work in their particular conditions. As a result, there is a danger that myths about supposedly effective technology could be perpetuated. Senior management of mining companies seem reluctant to devote adequate funds for R&D to provide technology needed to meet emerging requirements of industry. Mining is a cyclical industry and when it revives the needed technology, may not be ready to meet the emerging regulatory needs which will be stricter than before.

Sponsors are reminded that this report is strictly confidential--particularly information about mining and milling operations which, in most cases, was generously provided by the companies described. Not all the information reported here has been verified, however.

THE NEED FOR INFORMATION ON WATER MANAGEMENT/TREATMENT

There are several compelling reasons for mining companies to become more knowledgable about water management and water treatment technologies. The need depends greatly on geographic location and climate and could be one or more of the following:

- Scarcity of water for a mine or mill may at least partly be overcome by selecting a water-efficient process and creative water recycling and management. Alternative sources of water may be made usable for metallurgical purposes.

- Operations may generate excess water due to a wet climate or mine dewatering. Before discharge of excess water as an effluent, it may have to be treated to comply with regulations.

- Creative water management may make it possible to reduce the amount of effluent that needs treatment before it can be discharged, e.g., through cascaded use and reduction in fresh water intake.

- Knowledge of the impact of water quality on metallurgical process efficiency makes it possible to judge when process water should be treated and when alternative metallurgical processes should rather be selected.

- Even operations that were shut down years ago remain the responsibility of the original operators and owners, and it may be necessary to find cost-effective

remedial steps to restore the area affected and treat drainage water for discharge to receiving waters.

- Acid mine drainage is the most serious environmental problem of mining and milling. There still is no solution to this problem which avoids the need for "perpetual" maintenance of tailings and wasterock disposal sites or the need for water treatment plants to treat AMD from these sites for the next 300-500 years or more. Industry needs more information, firstly to become aware of the problem, secondly to understand its fundamentals, and, finally, as an aid in the search for site specific answers to the problem that are more attractive than the present approaches.

Even though there may appear to have been a "lull" in U.S. regulatory involvement in mine waste and mill tailings disposal at the federal level in the U.S.A., due to the temporary suspension of RCRA (hazardous waste disposal) regulations applicable to the mining and milling industry under the Beville Amendment, the operative word is temporary. The U.S. EPA is regrouping its efforts and reformulating legislation to deal with mining and milling wastes, and protection of surface and groundwater quality is high on their priority list.

At state levels meanwhile, permits are no longer granted or renewed unless the impact of a mine, mill, and all ancillary support facilities on the environment is fully understood in advance and minimized. Since water quality is the most important environmental impact of mining, permit grantors focus attention on the possibility of damage to surface and groundwater and how this will be avoided.

Focus on groundwater protection in mine/mill permitting is relatively new but has already become well entrenched in the trend-setting state of California and others such as Washington, South Dakota, and Wyoming. It is clear that recognition of the need to preserve ground and surface water quality and, hence, the need to protect usable groundwater resources from damage due to seepage from mine/mill wastes is spreading throughout the U.S.A. and to all the major mining centers of the world. Recent amendments to the Water Act in South Africa have been put forward by the Dept. of the Environment (formerly called the Dept. of Water Affairs) which include severe penalties, forfeiture of profits, and liability for damage claims where industrial activities cause damage to surface waters or groundwater beneath these operations. If enforced literally, these new amendments will have a major impact on both existing and future mining operations in South Africa. Brazil and Papua New Guinea are examples of third world countries where regulations are modelled on the U.S.A.

The new consciousness of the potential impact of mining and milling waste on groundwater will have a major impact on how mining wastes and effluents are disposed of. This has already created a growing demand for knowhow and technology for impermeable linings of impoundments for tailings and effluents and, in some cases, also for wasterock piles.

First examples may have erred on the safe side and have possibly been designed to be more expensive than they really need to be. Here is one example where a growing experience factor will make it possible to save on capital costs and still present a margin of safety. Experienced geotechnicians may be able to find a tailings site where natural base materials are such that the need for an impermeable lining can be avoided even within today's permitting framework.

Fortunately, the fact that tailings are to be deposited in a tailings impoundment or an effluent impounded or evaporated does not automatically mean that groundwater will be contaminated or that contamination per se is undesirable. Perhaps the aquifer already contains such poor quality water as to render it unusable in the first place. In such a case, there is little reason to protect it from further contamination. Second, many sites can be shown to be impermeable enough naturally to prevent seepage during the life of a mine and mill. Finally, even where the strata beneath the site are shown not to be impermeable, there are many sites where the natural geochemical nature of these materials is such that they will attenuate contaminants contained in the water that seeps through these layers and, in effect, the natural capacity of the subsurface materials may be adequate to remove all contaminants of concern during the life of the mine and mill thereby avoiding groundwater contamination. With respect to surface water contamination due to runoff, very often diversion ditches can be constructed to reduce the catchment area and, hence, the volume of impacted water. In order to obtain the maximum from the natural advantages of such features, the services of geotechnical engineers, geochemists, and hydrologists with special knowledge of these areas of expertise can be called upon. This is still clearly a developing science, but there have already been several notable successes. This report attempts to identify useful sources of expertise in these areas which form an important part of water management.

There are also significant indirect consequences of the new rules governing groundwater protection. For example, if in order to protect groundwater quality the tailings pond and recycle process water impoundments have to be lined, the water balance of an operation can be significantly altered. More importantly, perhaps, the salt balance of the operation will also be changed with a build-up of dissolved species in solution. Previously, where tailings ponds and impoundments did not need to be lined, very often these offered an effective and convenient bleed of both excess water and contaminants.

Buildup in concentrations of salts in recycled process water due to reagent additions or reactions with the ore itself may reach higher levels now which can have a significant effect on metallurgical recoveries. Industry has limited experience at quantifying this possible problem. To illustrate this point, consider for a moment two uranium mills, both recovering uranium by ion exchange after a sulfuric acid leach and solid/liquid separation. At Rössing Uranium Ltd., described in Appendix I of this report, tailings dam water is recycled as a water conservation measure. Seepage from the rather permeable tailings pond is collected by a series of cutoff trenches around the toe of the

large unlined impoundment and recycled to the process. The quality of this seepage water is significantly better than the tailings pond decant solution as a result of contact with the calcerous substrata which removes many of the undesirable contaminants. Rössing is unquestionably the most water efficient uranium recovery operation in the world and can operate on a zero discharge basis except for a minor seepage loss.

Dawn Mining, Washington, on the other hand, is located in an area with net precipitation. When its tailings dam was lined in 1982, a convenient water and salt bleed from the system was lost. The result was that tailings decant solution had to be used as process water and, during recycle, the TDS increased to the extent that uranium loadings on the ion exchange resins were depressed. Were it not for the timely decision to suspend operations due to poor uranium prices, a way of treating the recycled water would have to have been found if the emerging metallurgical problem was to be solved. This could have been addressed by various water treatment measures, possibly aided by changing the brand of ion exchange resin to select one that was less prone to silica fouling and more selective for uranium. In both cases, the increased use of recycled solutions resulted in the need for measures to overcome the greater corrosivity of recycled solutions.

Rössing Uranium in the Namib Desert and Dawn Mines in Washington state are but two examples of many that illustrate the significance of water management, water quality, and the impact on metallurgical recovery processes.

Despite the difficulties that now prevail in meeting new emerging regulations, new mines and mills are being developed in even the most strict of these locations--e.g., the McLaughlin project of Homestake Mining Company. Much can be learned from these new operations. Now it remains to find environment- and permit-compatible ways of achieving the same but at a more affordable cost.

Throughout this report, the reader should bear in mind the generally easier task as far as water management is concerned of operators in dry net evaporation climates as compared with those in wet net precipitation climates--that is, provided the operator in the dry climate has enough water to meet his needs.

OBJECTIVES OF THIS REPORT

The objectives of this report are to provide an insight into the present and future needs of the mining and metallurgical industry for water management and water treatment technology. The aim is to focus on what can be done rather than what cannot be done, and to lead sponsors to new technology possibilities, i.e., what may become possible with additional development work. The objectives of this report are:

1. To identify and describe useful technology and equipment for effective and economical water treatment--i.e., the state of the art.

2. To identify and describe new water treatment technology frontiers which, after additional development, may be engineered into useful and cost-effective water treatment processes.

3. To investigate and review the philosophy of water management and water treatment technology applications, and to demonstrate how a "systems approach" encompassing the mine, mill, wasterock dumps, tailings, and effluent impoundments may make it possible to achieve better metallurgical results while offering greater environmental protection at a lower overall cost. Such a "systems" approach may even include sewage sludges, treated sewage effluent, and municipal garbage.

4. To find examples of water management successes, failures, and pitfalls in mine-mill environments which provide a useful insight to industry.

5. To identify sources of expertise that can be called upon for help, both from within and outside the mining industry.

THE SYSTEMS APPROACH

Metallurgical plant design should take into account water quality and availability at the mine(s), mill(s), tailings impoundments, wasterock pile, smelter, refinery, effluent treatment plant, concentrate and ore stockpiles, and ore storage areas, etc., all of which should be regarded as one integrated system from a water treatment standpoint.

Gone are the days when miners were responsible only for mining, metallurgical engineers strictly for milling and refining, and environmental engineers for tailings management, water quality monitoring and treatment, if necessary. That kind of company is an endangered species today.

Metallurgical engineers can no longer escape the need for an intimate knowledge of water management and water treatment technology, applicability, and costs in order to select the best overall combination of metallurgical process and water management/treatment for a given situation. Environmental engineers must, on the other hand, learn enough about mineral processing to be able to suggest alternative approaches as well. The difficulty is that this requires multidisciplined experience which is only just starting to come back into style.

There are many examples of where a systems approach makes a major difference to overall cost. Several of these are discussed in the report. For example, the question of

selecting the best flotation arrangement for treatment of complex base metal (Cu, Pb, Zn) sulfides. Effluent discharge restrictions and contaminant limits mean that water should be recycled as much as possible to meet permit requirements as well as to avoid the need to treat more effluent than necessary. Historically, an often used metallurgical recovery approach was to float a Cu-Pb bulk concentrate. This was followed by addition to the bulk Cu-Pb concentrate of sodium dichromate (Cr^{VI}) to depress galena followed by selective flotation of a copper concentrate. Other reagents (e.g., CN^-) were added to depress pyrite, marcasite, and pyrrhotite in the process arrangement.

With the more recent need to recycle water, great care must be taken to seggregate process waters containing dichromate because if this reagent were to find its way with the main process recycle water to the point end of the process, lead recovery in the bulk float would be reduced due to premature depression of galena.

Another example is the question of thiosulfate generation in operations where active sulfide-containing ores are milled at a high pH. Also, thiosalts and thiosulfates are generated when SO_2 is used as a conditioner which is a common practice. Thiosalts can, at times, reach levels that, when discharged in effluents, subsequent natural oxidation results in pH reduction of the receiving waters to levels that are well below permitted limits. A variety of processes have been investigated for thiosalt oxidaton from effluents but with limited success. Possibly, the thiosalt effluent problem will be resolved by achieving almost 100% water recycle and by limiting thiosalt generation in the first place by avoiding or reducing SO_2 addition. Finding the best overall answer to the thiosalt effluent problem requires a <u>systems approach</u>.

An example, albeit an extreme case, was found where water to a mill was provided by the services department which reported to the mining division. Lake water of good quality was treated by lime-soda softening followed by ion exchange to make it suitable as boiler feed. Many years after the mine-mill complex started up, an expansion of the mill was contemplated at which point it was discovered that all process water delivered to the mill was also being treated through the softening/ion exchange plant--a significant unnecessary expense because a systems approach had not been adopted.

In gold and silver recovery operations, if an effluent has to be discharged, it will likely need treatment in North America for metals and cyanide removal if regulations are to be complied with. It costs a lot more to remove a pound of cyanide from solution than it costs to add it in the first place--several times as much, in fact, in most cases. Where "refractory" gold is recovered in a sulfide flotation concentrate, which is roasted and the calcine leached in cyanide, it is possible to reduce the volume of water requiring treatment dramatically by segregating the cyanided calcine leach tails and cyanide containing water from the main flotation tailings and effluent. If the cyanided tails and the main flotation tails are combined, the volume of effluent requiring treatment before discharge as an effluent will be greatly increased. Another advantage of the systems

approach in this case is that calcine leach tailings can be stockpiled for future reprocessing. Also, most gold plant effluents and tailings contain residual values that are worth recovering as an incremental resource. If a "systems approach" is adopted, the metallurgical pros and cons of installing the recovery system before or after cyanide removal are taken into account as well as the merits of treating recycle solutions from the tailings plant for gold recovery before recycling solution to the plant. Normally, recycled gold tailings decant solutions contain valuable residual cyanide and lime values, but in one interesting case, cyanide is removed from recycle solution prior to its return to the plant in order to improve gold recovery.

One operation treats their combined minewater and mill tailings decant and seepage water flow. Another, not far away, uses their metals-contaminated minewater as mill water. The high pH in the mill precipitates undesirable metals and neutralizes the acid thereby consuming some lime at a cost, but at a far lower cost, than the installation and operation of a special treatment facility.

These and many more examples of a "systems approach" are discussed in the report.

DEFINING THE PROBLEM

The mining and metallurgical industry faces many environment-related problems, especially but not only in the U.S.A.

The U.S. regulatory and legal structure relating to environmental protection and permitting of operations is unwieldly and, in many cases, is impractical and counter-productive. It is almost as though the rules were written by lawyers for lawyers with litigation and proliferation of legal work in mind rather than to find suitable ways to protect the environment as well as the mining industry. In the opinion of this author, it will take a major revamping of the whole regulatory system and the regulations themselves to create a meaningful set of site and industry-specific environment protection rules for the mining and metallurgical industry in the U.S.A.

The present regulatory and permitting system as well as the CERCLA (Superfund) rules governing recourse for damage incurred in the past, even before the rules were enacted, is a contributory factor in the current demise of the U.S. exploration and mining industry. At this time, when the strong U.S. dollar discourages foreign investment in mining and exploration in the first place, and commodities are less expensive to import from abroad than to mine in the U.S.A., the additional unwieldy and often unreasonably restrictive permit and regulatory requirements are very discouraging and are part of the cause of the current depression in the U.S. mining industry.

Furthermore, as the federal government increasingly delegates the authority of regulating and policing environmental aspects and permitting of mines and mills to state and local authorities, the requirements vary dramatically from one part of the U.S.A. to another depending on how much local agencies "favor" or "disfavor" mining activities in their midst. The ease of permitting an operation and the time it takes to obtain a permit also tends to increase when the state and local officials have limited experience in dealing with this type of industry--as, for example, when permits were sought for a large new gold mine and mill in the state of Washington or when a major oil company sought to get a permit for a copper-lead-zinc mine and mill in Wisconsin. In these cases, a lengthy education process for the regulators is needed before they are knowledgable enough to be able to formulate regulations. Often, the first drafts of such permits are based on a biased image of the mining industry, and demands are made for the impossible.

This report examines the present regulatory climate and system in several parts of the world. It has not been possible to come up with a formula for instant success in all of them, but some interesting insights and suggestions have been possible.

This investigation has tried to step back and ask the question: What are the real major water-related problems that face the mining and mineral processing industry? Some of the problems as presently perceived seem to be a storm in a teacup. Yet, others do appear to be more serious than is presently realized and will present a major economic burden on much of the industry for centuries to come unless better ways of managing and disposing of tailings and effluents can be developed. This report provides a more global perspective as to where the real needs for new environmental technology lie and why. In this respect, acid mine drainage has been identified as a universal problem requiring more satisfactory technical solutions.

THE CHALLENGE

There are clearly unresolved environmental compatability aspects of mining that have an impact on water management practices and which are affected by water management. These need urgently to be addressed. There are five important challenges that need to be responded to at this time with respect to water management and treatment technology:

Challenge 1

Acid mine drainage is a real problem that needs a technical answer that will not be provided by more regulation or through litigation. Industry needs to find and tackle the root of the problem and not just the symptoms.

Challenge 2

Realistic and practical regulations are needed which protect the environment and water resources while allowing the mining industry to survive. These need to be formulated in a more circumspect way than before. This will require cooperation and perhaps leadership from the mining industry itself and much less involvement by lawyers, particularly those in and around Washington and state capitols who frequently know little about the environment and less about mining and technology for water treatment. All too often, delays in permitting result from inexperienced regulators who first have to become informed. Mining companies can help speed up the permitting process if they themselves are well enough informed to provide guidance that the regulatory agencies often need.

Challenge 3

Improved water management concepts and technology as well as more cost-effective water treatment and safe precipitate sludge disposal methods are needed. Adopting a "systems approach" would fall into this challenge. Another part of this challenge is to adapt technologies to make them compatible with the needs of the mining-metallurgical industry. Remember that though prevention is better than cure, effluents are the symptom, not the cause of the problem.

Challenge 4

This is a philosophical challenge in which the mining industry and regulatory authorities and bureaucracies need to come together to find and apply affordable and practical technologies. As knowhow evolves, there will be a further need for plant-scale experimentation and demonstration of emerging technology. This cannot be done if results must be guaranteed in advance as is required in the present permitting process (with a few notable exceptions). The change in philosophy must be toward cooperation in finding technological answers to practical problems rather than resorting to litigation, confrontation, and mistrust.

Challenge 5

Senior mining company management needs to stop regarding anyone genuinely interested in the environment as an "environmentalist" and, therefore, automatically suspect of being a threat to industry. It is suggested that part of the solution to the "environmentalist" problem is to nurture a breed of "informed environmentalists" who base their opinions on scientific facts and real data as a counter force to the kind that bases its actions on emotional notions or to serve bureaucratic power struggles.

THE OPPORTUNITY

Several opportunities are emerging in connection with water management and treatment at this time. First, the regulatory requirements for environmental protection in opening a new mine or mill are today so complex, particularly in the U.S.A., that fewer companies are equipped to entertain such projects in several parts of the country at the same time. This means that there will be investment opportunities abroad where environmental protection regulations are still more reasonable to fill the supply gap. Within the U.S.A., investment opportunities will be more attractive for those companies that are successful at developing cost-effective water management and treatment technologies.

The level of technology used for water treatment in the mining and metallurgical industry is currently rather basic and rudimentary. There are several opportunities to develop innovative improved water treatment technologies and water management knowhow that can save costs and yield better results. There are numerous R&D frontiers and opportunities to develop patentable, useful technology and devices which will become a profitable endeavor in years to come.

The regulatory framework with respect to mine and mill waste disposal has (in this author's opinion) evolved in the U.S.A. into a counter-productive system that serves neither the environment, the national economy, nor the mining industry. There must eventually be an opportunity for the mining industry to take the lead in formulating a new set of useful rules that serve everyone's interests. First, particularly in the U.S.A., what is needed is much less government.

THE SNAG

Only during the last decade have very powerful new instrumental analytical methods become available which make it possible to measure many contaminants to below 1 ppb. As a result, environmentalists, regulatory experts, and universities are now able to measure the environmental effects of contaminants at various levels down to sub ppb concentrations.

Based on these findings, water quality objectives are being set and effluent limits established.

The snag is that practical technology applicable to the mining and milling of ores in remote locations and often in difficult climates, has not kept pace with the rapidly evolving laboratory work mentioned above. Water treatment processes in use at this time reduce metal contaminants to more like ppm levels than ppb levels.

Based on the legislated need to apply "the best practicable technology" and "the best achievable technology, BAT," there is the distinct danger that every time a university professor announces an apparently improved technology based on laboratory scale tests, that this will be incorporated into BAT regulations as the prescribed effluent treatment process. In field conditions, or for solutions containing other spectra of contaminants, such processes may not be workable. Government needs to provide industry support to develop and test such technologies with participation by everyone involved and to nurture a team spirit. In this respect, an excellent example has been set in South Africa. Pilot testwork and field tests on a full scale to demonstrate new processes are very expensive. Companies must always bear in mind an alternative course of action that they can take if once their new mine/mill has started up, and the prescribed new water treatment process fails to perform in practice as it did in the pilot tests. This adds a new element of risk to mineral processing operations in the U.S.A. and elsewhere.

THE APPROACH

The approach taken in this investigation has been to visit about fifty mine-mill complexes and to describe their water management and water treatment challenges and innovations. These trip reports are documented in Appendix I. Based on these and the gathering of information through literature searches and discussions with numerous technology development organizations, suppliers, and mining companies, the status, needs, and technologies available to deal with water problems are reviewed.

An attempt has been made to find out and document for the reader of this report just what the current state of the art is, what needs for technology are emerging, and where he can go for help.

Other RANDOL multi-client reports have included a list of consultants and engineering contractors serving the industry under investigation. In this case, there are too many facets for such a composite list to be very useful. Consequently, expertise and engineers have been listed in each chapter in the context of their special expertise. Likewise, references are mentioned at the end of each chapter to keep them in context. The last chapter in this report lists what have been concluded to be the most important frontiers for further research and development in this pioneering area of technology.

GUIDING RULES

Three guiding rules have been followed:

1) This report concentrates on <u>what can be done</u> and on identifying technologies of potential value but which may need further development.

2) If a water treatment process is going to be useful in the mining and mineral processing industry work environment, it should be SIMPLE.

3) PREVENTION of water contamination is better than CURE.

WARNING

1. The water management and water treatment science is still at an early point on the learning curve--it is an immature science. Readers are warned that hearsay observations and comments were often the best or only source of information available, and much of it may be unreliable. Information in this report should be used as a guide subject to testing of sponsor's site-specific conditions.

2. This report and its contents are strictly confidential and should not be reproduced or distributed in any way. If serious errors or misinterpretations are identified, these can be rectified by distributing corrections and errata to sponsors.

INTRODUCTION

There is no question that unless protective measures are adopted, mining and mineral processing operations will nearly always have an impact on water quality and the environment.

The Kam Kotia abandoned mine and tailings site near Timmins, Ontario, is one example of the type of environmental damage that is caused by a mining operation when an abandoned mine-mill site gets out of control. In this case, the abandoned acidic tailings dam has ruptured, and all vegetation in its path denuded for several miles; tailings have been distributed for miles resulting in further distribution of windblown dust during dry spells. Also, a lake and many miles of river system have become non-viable to all except the coarsest of fish. In addition, the aesthetic impact on this otherwise pleasing landscape has been such that few would wish to see similar events repeated. Fortunately, few have witnessed this sight.

Another famous example is the condition of Whitewood Creek at Lead, South Dakota, before and after environmental controls were employed. Who can deny the remarkable transformation that Homestake Mining Co. and the Lead community have achieved. The creek today supports a trout fishery and, perhaps more importantly, is a pleasant place to be.

The influence of mining and mineral processing on water quality and the environment varies greatly from site to site, and also from one climatic region to another. Whether or not that influence constitutes damage or a nuisance also varies from location to location depending on the nature of the environment to begin with and a host of other factors. For example, a major distinction can be made between locations with a net evaporation and those with net precipitation.

It is beyond the scope of this investigation to probe whether the damage caused by mining and mineral processing is of a greater or a lesser magnitude than the damage to industry and to the national economy of the U.S.A. and, therefore, to the wellbeing of its citizens, of unconstructive, impractical rulemaking and regulation of the industry out of context with the environmental benefits gained. Those who claim that mining and mineral processing damage to the environment is negligible and does not require regulation are as unrealistic as those who believe that profit-motivated free enterprise is wrong, and that the North American mining industry should be inhibited or stopped altogether, if possible, through regulations and permit requirements.

Before discussing a host of new technologies in mining and tailings disposal which have a very positive effect on controlling water pollution and environmental damage from mining and milling operations, it is proper to ask what the nature of the type of damage that can be done by the mining and mineral processing industry to water resources and to the

environment are. An answer to this question is necessary if we are to objectively review what remedial measures are needed. Society as a whole must work toward supporting those protective measures that make real sense while those that serve only the perpetuations of the bureaucracies that create regulations must eventually be abandoned. The difficult part is to have adequate knowledge and data available to be able to distinguish wisely between the two.

An important source of data on the nature of mine and mill wastes and their impact on water quality is the PEDCo (1983) study report which is a primary source of evidence on which the U.S. Congress will formulate federal regulations under the RCCRA laws. PEDCo Environmental, Inc. was commissioned by the EPA to sample a wide variety of tailings, waste rock, sediments in ponds, minewater, mill processing solutions, etc. at several operations in each of the main mining and mineral processing regions of the U.S.A. Leach tests using water and the EP leach test were performed on solid materials and groundwater samples taken.

PEDCO ENVIRONMENTAL, INC.
11499 Chester Road
Cincinnati, OH 45246

Although there are obvious flaws in the PEDCo report, particularly with respect to sampling of groundwater, it is remarkable, in reviewing this data, how little impact the tested cases have had on surface and groundwater quality in their vicinity. The PEDCo study did find several cases where water quality was impacted, but nothing which could not be sorted out through the use of more efficient impoundments. One of the important conclusions that can be drawn from a review of the PEDCo data is that water quality impact by mine and mill waste is very site specific and, even within one branch of the industry, e.g., copper mining, the impact will vary from case to case. Also, natural processes are both useful and powerful in mitigating some of the environmental and water quality impacts of mining. The PEDCo study sampled operating mines.

A second useful source of information are the reviews by such organizations as the U.S. EPA and ONTARIO (1979) which document the rationale for their selection of ambient water quality objectives.

WAYS IN WHICH MINING CAN EFFECT THE ENVIRONMENT

Mining and mineral processing can affect the environment in the following ways:

1) Acid Mine Drainage (Including Non-Acid Mine Drainage)
2) Reagents Used in Mining and Mineral Processing
3) Metallurgical Process Solution Effluents
4) Organics, e.g., Lubricating Oil, Diesel, Grease, Hydraulic Fluids

5) Suspended Solids
6) Temperature
7) Alteration of the Water Table and Local Hydrology

ACID MINE DRAINAGE

Acid mine drainage (AMD) is generated from both open pit and underground mines, wasterock, and tailings where water and air come into contact with sulfide minerals. Acid mine drainage is a universal problem in mining and metallurgical operations and in the estimation of RANDOL INTERNATIONAL LTD., is the most significant cause of water quality and environmental damage. One of the most alarming aspects of AMD is that it will continue to be generated for centuries after the mine-mill operation that generated the tailings has been closed unless site specific better ways of disposing of sulfide-bearing wastes are found.

Acid mine drainage occurs in the coal mining industry, uranium mining and milling (e.g., the Witwatersrand and Elliott Lake), gold and silver recovery, the mining and milling of complex and massive sulfide minerals, e.g., copper, lead, and zinc mines on the Canadian Shield, and elsewhere where ores can contain up to 60-75% iron sulfides. Originally, AMD was believed to be a phenomenon associated with only coal mining, but this has turned out to be far from true.

AMD may not be immediately obvious when an operation starts up as it takes up to several years for the accumulating wastes to oxidize before runoff and seepage become noticably acid. Once it becomes acid, the generation of more acid mine drainage seems to accelerate.

AMD is much more of a problem in those parts of the world with a net precipitation, i.e., a wet climate or one with a heavy snowfall. In arid regions where water is scarce, contaminated water can be segregated and evaporated, and tailings disposal methods which encapsulate acid generating species may be developed more easily than in wetter climates. In some such arid environments, for example the Grants Uranium District, there is an excess of minewater that must be pumped from underground, and this water must be treated to remove radium before it is discharged to a "creek" from which it seeps back into the mineworkings.

Where there is a net precipitation, AMD water accumulates in impoundments until a point is reached where it has to be released. In order to treat AMD, usually a lime neutralization and settling plant is needed at the site of such tailings and wasterock piles in perpetuity, which has been calculated to mean for the next 300-500 years. AMD introduces sulfate and hydrogen ions to water that comes into contact with these materials. Heavy metal ions can also dissolve in the AMD which then may become an

environmental liability. Another AMD contaminant which can cause severe damage to aquatic ecologies is ammonia which finds its way into minewater through the use of underground explosives and which is very costly to remove or oxidize in large AMD flows. Even if acid mine drainage is treated with lime to neutralize it, there will still be the introduction to the system of calcium sulfate ions and others which may or may not be a problem.

Sometimes the naive argument is raised that in nature, eventually ore deposits containing sulfides will be eroded into by natural forces which will result in their oxidation and the generation of acidic water which will discharge to the environment. This is certainly so, but the time frame over which a sulfide ore deposit will be oxidized in nature will be much longer than when it is mined, and large volumes of wasterock and mill tailings are exposed over a short period of time. This argument could, however, be realistically used in favor of the development of tailings disposal techniques which allow the controlled release of contaminants within the limits that can be tolerated by the receiving waters or the environment generally.

THE WITWATERSRAND - ACID MINE DRAINAGE

In some parts of the world, it is the pH reduction that is considered environmentally undesirable. In others, it is the acidity and also contained base metals such as copper, lead, zinc, etc. Elsewhere, particularly the Witwatersrand area of South Africa, acid mine drainage pumped from deep underground mines contributes high levels of total dissolved solids to the regional water supply in the Vaal Dam. Minewater containing typically 6,800 mg/l TDS before neutralization is neutralized using lime after which its pH is raised to around pH 6.8, and the TDS dropped to 5,000 mg/l. TDS in the point source discharge of minewater pumped from a few large mines contributes about 30% of all TDS from point sources in about 12% of the water volume that flows into the Vaal Dam.

In addition, an as yet unmeasured volume of diffuse source drainage from sand and slimes dumps also drains into the Vaal Dam. The lower level of TDS in this water has been measured at pH 3.1 and 6,200 mg/l TDS, while levels up to 51,000 mg/l tds at pH 2.4 have been reported by KEMPE (1983). BROWN (1981) estimated that the quantity of sand in the top nine-meter layer of just one of the 30 large sand dumps scattered around the Witwatersrand ammounted to 5,705,000 tons from which 57,676 tons of sulfur (at 1.01% sulfur) was available for AMD formation which would yield 176,333 tons of pure sulfuric acid on oxidation. Assuming that this acid was generated over 25 years, this dump was producing about 7,000 tons of pure sulfuric acid per year. KEMPE (1983) estimated that the 30 sand dumps on the Witwatersrand contain up to 26 million tons of sand each.

The sand and slimes dumps on the Witwatersrand cover a total area of about 80 square kilometers. Mines established after about 1918 adopted the all sliming cyanidation method

of gold extraction. This resulted in the elimination of sand dumps and their associated serious water pollution problems. However, sand treatment on established mines continued for many years, and the last one was phased out in the sixties.

Slimes dams, because of the finer division of the tailings contained in them, are very much less porous than sand dumps. Consequently, seepage is also much less. Leaching of pyrite, according to KEMPE (1983) does not appear to penetrate to depths in excess of about 3 meters. Runoff water on top of slimes dams becomes considerable, but it is relatively simple to control and retain it for evaporation. Unfortunately, there was little control of this surface runoff water in earlier days, and it caused serious erosion of slimes dams. On modern operating slimes dams, excess water is drawn off through penstocks and returned for reuse. Trenches are provided to drain any seepage to the penstock pumps.

On the central Witwatersrand area, there today remain three large mines and three smaller concerns. In addition, there are about seven companies that exploit residual gold in surface dumps and slimes dumps. In order to allow underground operations to continue, it is necessary to maintain underground water in the whole Witwatersrand below a critical level. This is achieved by pumping water from the three larger operating mines, Durban Roodepoort Deep, East Rand Proprietary Mines (ERPM), and Grootvlei, the latter pumped via South African Land and Exploration Mine (Sallies) on which the huge East Rand gold and uranium dump reclamation project (ERGO) is situated. All water underground drains to these four points.

Water pumped during the year preceeding August, 1979, contributed 30% of the total 272,000 ton salt load from point sources reaching the Vaal Barrage according to the Water Research Commission (1979). KEMPE (1983) suggested that seepage from the sand dumps and slimes dams no doubt contributes significantly to the 47 percent of the non-point loading and is probably largely responsible for the surge in salt loads experienced at the onset of the rainly season when there appears to be a "flushing out" of salts accumulated during the dry winter months.

According to KEMPE (1983), ERGO's intake water in 1978/79 ammounted to 21.4 million m^3 per annum with a salt load of 38,200 tons which is mostly derived from the Sallies supply of 60% of total and has a TDS content of about 2,000 mg/l. Effluents discharged by ERGO had a salt load of 33,500 tons of TDS to the Barrage in 8.6 million m^3, i.e., a TDS content of 3,895 mg/l which alone constituted 12% of the total salt generation to the Vaal Dam. As described in Appendix I, ERGO is, of course, working on every possible way to reduce this.

The mines referred to by KEMPE (1983) include only the small number of the remaining mines between Roodepoort and Springs, constituting the central and eastern Witwatersrand. About 30-35 additional mines are located in other parts including the west

Rand stretching from Krugersdorp to Klerksdorp and the Orange Free State gold fields. These latter operations do not drain into the Vaal Dam directly although, with the proposed reversal of flow of the Vaal River downstream of the dam back into the dam, drainage from all the mines from Johannesburg to Klerksdorp would in the future possibly drain into the Vaal Dam.

In the area west of Johannesburg, the Witwatersrand ore sequence is overlain by a series of dolomitic sedimentary rock which is porous enough to host a major deep regional aquifer. Mine and mill operations are located on the surface on top of the dolomite formation as well as large slimes dams generated over several years. In recent times, the dolomitic aquifer has been proposed as a location for storage of usable municipal water which could be replenished during years of "plenty" and drawn from during years of drought. Due to the geology and climate of the area, there is a second principal aquifer over much of the area. This is a near-surface, sometimes non-perennial aquifer which is normally in hydraulic continuity with the surface water of the area when present.

The latter aquifer, developed due to the intense weathering of the surficial rocks of the Witwatersrand which were lain down over 2,000 million years ago, is highly permeable and relatively vulnerable to surface pollution. Slow leakage may or may not occur from this near-surface aquifer to the deeper, regional groundwater. The disposal of cyanide-bearing gold tailings can represent, according to SMITH, et al. (1984) a potential pollution threat to both quifer regimes by direct runoff, erosion of tailings, and seepage from the tailings impoundments themselves.

Certainly, where mineshafts and deep drillholes connect the surface with deep underground mineworkings in the area, there may be adequate hydraulic connection between the two aquifers to transport contaminants to the lower dolomitic aquifer.

SMITH, et al. (1984) also compare TDS and sulfate concentrations found in tailings interstitial waters with "background" groundwater levels from several tailings dams as follows:

	TDS	SO_4	Fe	Mn	pH
Dam 1, ±5 Years Old	712	317	0.1	15	6.8
Dam 2, Over 20 Years Old	500	400	34	69	2.9
Dam 3, ±20 Years Old	300	70	4	0.8	5.8
Dam 4, ±10 Years Old	500	-	-	-	7.5
"Background" Water Quality	250	50	0.1	0.1	7.8

Based on their preliminary data, it appears that acid mine drainage in seepage from slimes dams may be less than would be expected, especially where these dams are placed on the naturally occurring, low-permeability clay layer that occurs in much of the area. It has

INCREASING TREND OF TDS CONCENTRATION AT THE RAND WATER BOARD'S VEREENIGING INTAKE

suddenly become important to protect the quality of this aquifer and, for the first time, a real interest is being shown in the impact of mining, milling, and tailings dams in the area on the quality of these dolomitic aquifers.

Surveys are presently being undertaken on behalf of the Water Research Commission by a South African firm of geotechnical engineers to assess the impact of model slimes dams on seepage into this groundwater resource. The survey by Steffen Robertson and Kirsten has yet to be completed, and results have not yet been published. However, SMITH, et al. (1984) reviewed, in general, preliminary results of a survey of cyanide levels in groundwater below gold mill tailings dams including those located over the dolomites and commented on the apparent lack of contamination of the groundwater regime, even in close proximity to the impoundments. They suggested that there are several possible processes which may be responsible for the breakdown and/or fixation of cyanide removed from the aqueous system in the tailings and preventing groundwater contamination:

- The method of tailings disposal: the so-called "semi-dry" or "sub-aerial" disposal technique.

- Prevalent climatic conditions.

- The presence of oxidized iron in the tailings and in the highly weathered, semi-lateritic or lateritic near surface aquifer may remove cyanide from solution and serve to co-precipitate several other unwanted metal ions as well.

It is also possible that vertical transport of dissolved salts by capillary action to the surface of slimes dams may result in a perennial contamination of surface runoff water which may be more easily controlled and evaporated than seepage.

As much rainfall runoff as possible is caught in the catchment area of the Vaal Dam and soon, water draining into the Vaal River below the dam will also be used as the main regional water supply serving the growing metropolitan-industrial area around Johannesburg. Vaal Dam water is treated for the removal of impurities, i.e., suspended solids, iron, base metals, etc. These are all relatively easy to remove. The problem lies in the buildup of TDS, mainly of such species as $SO_4^{=}$ and Cl^- which are not removed in standard water treatment processes. Records since 1935 of the average TDS in water at the Vaal Barrage show a steady increase from around 150 mg/l in that year to around 800 mg/l today with peaks close to 1,500 mg/l. Clearly, the drainage system is being overloaded by the impact of industry and the large population. According to HENZON (1983), a recent estimate by the Water Research Commission concluded that the present TDS level in the water supply adds about $680 million annually in cost to society in terms of corrosion, extra detergent needs, and water purification needs. A total of 520,000 tons per year of dissolved solids enters the Vaal Dam from the catchment area of which over 75,000 tons per year came from just three minewater pumping stations.

Sand and slimes dams of the Witwatersrand

TABLE 6. Salt loads generated in Barrage Vaal Catchment: September 1978 to October 1979
(i.e. Difference between intake water and effluent loads)

Source	Flow Volume ($m^3 \times 10^6$)			Annual salt generation (Tons)	Per cent of total
	Intake	Discharge	Net generation		
E.R.P.M.	6,4	13,3	6,9	55 300	
Sallies (excluding supply to ERGO)	0,7	3,1	2,4	7 300	
D.R.D.	4,0	4,5	0,5	12 700	
Grootvlei	1,3	4,4	3,1	7 100	
Sub-Total Mine Pumpage	12,4	25,3	12,9	82 400	30
Sub-Total Six Municipalities	290,7	185,8	-	55 700	20
Sub-Total Industries and Statutory Bodies (includes ERGO) *	73,2	36,9	-	7 700	3
Non-Point Sources (calculated from modelled salt generation rates)				127 000	47
Total				272 800	100

* Details of salt generation by Industry and Local Authorities which includes ERGO, show ERGO to have a small negative quantity.

If it were not for the huge metropolitan center that has grown up around the Witwatersrand mines, the drainage discharge to the Vaal River would not be a problem as the Vaal would serve as a bleed to the ocean. It is only in the context of the whole integrated water system in which the TDS are recycled on macroscale that the salt addition, now seen as an incremental load, becomes critically important. New environmental regulations with respect to water seek to force the mining industry to bear the cost of treating this water.

ELLIOT LAKE URANIUM TAILINGS - ACID MINE DRAINAGE

The Elliot Lake uranium ores consist of quartz pebble conglomerates remarkably similar to the Witwatersrand ores. Elliot Lake ore contains 2-4% sulfide. These ores are typically ground to 50% minus 200 mesh (74 m) which is coarser than the Witwatersrand tailings which are comminuted to 80% minus 200 mesh. Just one of the Elliot Lake Mines, namely Denison Mines Ltd. at Quirke Lake, has already processed 25 million tons of ore, and a further 100 million tons will be mined. This mine-mill alone will yield 125 million tons of tailings containing 2.5-5.0 million tons of oxidizable sulfide. Regulatory limits control radium concentrations and the pH of the final effluent returned to Quirke Lake, but there are no limits on TDS or $SO_4^{=}$.

In this case, the readily oxidizable tailings are disposed of for the most part, above ground level starting off in depressions formed by local lakes and building up in height through the construction of dam walls to contain the slurry.

Acid mine drainage at Elliot Lake tailings impoundments are quite apparent. A steady bleed of sulfuric acid generated by the oxidation of 2-5 million tons of sulfur in these tailings over the next 100-200 years must go somewhere. Vertical migration of salts to the surface of the tailings is one way the dissolving salts are transported. Surface salts are then washed away annually with the spring runoff and dispersed.

The acid mine drainage problem is under intense study by several groups including one established especially for the purpose at Elliott Lake by the Atomic Energy Control Board.

Currently, acid water decanted from the tailings ponds is neutralized using lime, and the decant is discharged to the lake system. However, the prospect of continuing to neutralize acid drainage from these tailings, which are growing larger and larger, "in perpetuity" until all the sulfide has been oxidized is somewhat unrealistic.

Acid mine drainage inhibition and treatment is discussed in a separate chapter. This example serves only to illustrate the scale of the impact of mining this type of ore on the environment. The composition of tailings decant solution after neutralization and $BaCl_2$ treatment for radium removal is reported as follows:

	(mg/l)
pH	8.2
Radium-226	3.3 p Ci/l
NH_3	60
NO_3^-	81
TDS	2,852
$SO_4^=$	1,572
Cu	0.02
Pb	0.11
Zn	0.02
Ni	0.12
Co	LT 0.02
Mn	0.44
Ca	509
K	80
Cl	110
Fe	0.35
Na	87
U_3O_8	0.01

A good additional source of further information on the uranium mill tailings acid mine drainage problem is Gordon Ritcey at CANMET who has been involved for many years in trying to find an improved method for uranium tailings disposal that can avoid the generation of acid on a long-term basis.

At Elliot Lake uranium tailings areas, a new source of AMD cause was observed. Tailings deposited in above-ground ponds are subject to wind erosion. Sulfide-containing tailings are prone to windblown distribution which results in the distribution of acid-generating tailings over a wider area, perhaps beyond the tailings catchment area within which the acid mine drainage is collected. Establishment of vegetation on the tailings areas would be one way to avoid this problem, but this is not always easy, especially after oxidation and acid generation has started.

BASE METAL AND GOLD MINES, CANADIAN SHIELD AND BRITISH COLUMBIA ACID MINE DRAINAGE

Stretching across the Canadian Shield from Quebec through Ontario and into Manitoba there are numerous gold and base metal mines, most of which are associated with pyrite and other iron sulfide mineralization including pyrrhotite and marcasite. These operations generate wasterock and sulfidic tailings on a large scale which, together with minewater pumped from underground, contribute large quantities of acid drainage. The acid water generated contains several base metal contaminants as well as acid and sulfate ions. HAWLEY (1980) has reviewed the chemical characteristics of the mineral tailings in the province of Ontario.

Eastern Canada has a net precipitation and holds huge amounts of fresh water in a very extensive river and lake system. When maps of Canada in normal atlases are examined, one can see the Great Lakes which hold large volumes of water. It is only when large-scale maps of the individual provinces are examined, however, that one can grasp the large percentage of the surface of Canada covered by fresh water lakes, rivers, and waterlogged muskeg. Canada, in fact, accounts for around 37% of all the fresh water in the world.

Every spring, the snowmelt flushes the whole system, draining to the Great Lakes and untimately down the St. Lawrence River to the Atlantic Ocean. North of the watershed located south of Timmins, Ontario, the whole lake and river system drains to James Bay in the north and, again, the annual spring melt flushes the system out.

On the Canadian Shield, there has been considerable glaciation, and the result is that bedrock is covered by a generally shallow layer of alluvium. Canadian mining people point out that groundwater resources are small compared with surface water and that the groundwater aquifers are localized in bedrock basins which prevent widespread contamination of groundwater.

The nature of the regional hydrology and water use is very important when it comes to discussing or considering the impact of mining and mineral processing and, hence, acid mine drainage on the environment.

In a situation such as in Canada, the huge turnover of water from year to year would likely tolerate a much higher total salt load than, say, the situation in the Witwatersrand where as much runoff as possible is caught for reuse in the regional water supply.

HAWLEY (1979) has discussed the chemistry of acid mine drainage in Ontario. No concise list of AMD-generating operations or surveys of the extent of AMD generation in Canada was found, but in the course of this investigation, several operations in Canada were visited, and the AMD-generating capacity of their tailings and wasterock piles was obvious and awesome.

In British Columbia in the Canadian Rockies, there are numerous copper-molybdenum operations. These are located in areas with rain and snowfall well in excess of evaporation. Because drainage to the ocean is along important salmon fishing rivers, there is a considerable concern about any factors that could possibly affect the river habitat and spawning grounds. At several Cu-Mo operations, the water level constantly rises as precipitation accumulates in these ponds which are AMD generators. One example of such an operation is the Brenda Mine, but there are several others.

The AMD problem of tailings from these operations in British Columbia lends support to the concept of disposing of such tailings in deep lakes or in the ocean deep enough that oxygen levels are depleted to the extent that AMD generation does not occur. There is still debate on the effectiveness of deep lake or submarine tailings disposal as a means of avoiding or minimizing detrimental environmental effects.

AMAX, INC. operates a copper-molybdenum mill in British Columbia which disposes of tailings to the ocean which could possibly now serve as an example for detailed study to determine what, if any, impact on the marine environment there has been.

US BORAX has also extensively evaluated all aspects of submarine tailings disposal which is envisaged in the development of their enormous Quartz Hill molybdenum deposit south of Ketchikan, Alaska. Their operating plans have been under very careful scrutiny as this mine is located in land that was proposed as a wilderness area. Those interested in submarine tailings disposal could expect to find useful information in the Quartz Hill Project Environment Impact Statement which is available from libraries in Alaska--probably at Ketchikan, and also possibly from:

WESTMIN RESOURCES mines and mills a complex, copper-lead-zinc ore containing gold, silver, and cadmium at a site inside the Strathcona Provincial Park on Vancouver Island. Since 1967, WESTERN MINES has disposed of their tailings to the bottom of Buttle Lake after alkaline chlorination to destroy residual cyanide values. Buttle Lake is the source of the drinking water for the town of Campbell River (ECCLES, 1977). Information on this successful operation and perhaps a reading on the impact on the lake environment as a result of tailings disposal over the last 17 years might be available from the company; alternatively this site might be considered for detailed study of such impact.

WESTMIN RESOURCES LTD.
Campbell River, B.C.
A. G. Eccles
Mill Superintendent

It has been learned that more recently WESTMIN RESOURCES LTD. has stopped deep lake disposal and replaced it with a sub-aerial disposal technique, but no details as to why this change was made were obtained. Mining and milling operations affect the environment in several ways. Examples were encountered where groundwater was contaminated by acid mine drainage at an Ontario base metal recovery operation. The problem was solved by injecting fresh lakewater to the aquifer and removing the source of contamination.

The basic cause of the AMD is a pond in which mill effluents and smelter-scrubber water was contained which allowed sulfide mineral particles to settle. Over the years, the accumulation of sulfide particles in this pond became a source of AMD which contaminated groundwater from which potable water was drawn by a well.

At another location at a railroad loading point, a groundwater well was also contaminated by AMD as a result of seepage from the surface on which, over the years, concentrate had spilled during stockpiling and loading operations. This could have been avoided by preventing the spillages or lining the area, and the problem was solved by picking up the top several inches of soil and processing it through the flotation plant, as well as repairing the leaking railcars.

A major base metal producer in Ontario uses a series of large lakes as their tailings impoundment area and water stabilization and treatment facility. By increasing the volume of water in the impoundment areas, effluent levels of metals have been diluted slightly. An important observation was made between the effluent decant point and the receiving water discharge point. The treated effluent stream flows alongside a half-mile stretch of roadway constructed of wasterock. In this short stretch of stream, the nickel level in the stream increases 10% from 0.9 mg/l to 1.0 mg/l, illustrating the AMD-generating power of wasterock and the need to control the use of wasterock as fill for work areas, roads, and railbeds.

COAL MINING - ACID MINE DRAINAGE

Coal mines all over the world generate large quantities of wasterock or culm which is disposed of in culm banks. Sulfides as pyrite or as organic sulfur compounds occur commonly in coal and coal waste, and acid mine drainage is a very severe problem in both open pit and deep coal mines throughout the world. Measures to inhibit or treat acid mine drainage in coal mines in North America and in South Africa are discussed in chapters 23 and 24.

Because coal mining is such an enormous industry, the impact on the environment has been very serious. There is not much difference in the effect of acid mine drainage from various types of mines--all of it is acid, kills fish and vegetation, and limits the use of the water due to its TDS content.

The coal industry was not surveyed in detail in this investigation as few of the sponsors are interested in coal. Nonetheless, coal mining has had a major impact on the environment. This led to the passage by the U.S. Congress of the Federal Coal Strip Mine Act which centralized the regulation of surface coal mining in Washington, removing authority and power away from state agencies and coal operators, and resulting in the formation of a new agency, the Office of Surface Mining, which was formed to oversee this new regulatory empire.

Certainly, the coal mining industry found itself entangled in a new web of regulatory problems, but this might have been avoidable had the industry been more effective in policing itself and reducing the impact it had on the environment.

In Appendix I, descriptions of Burnside and Northfield Collieries outline some very effective measures that were taken to reduce the environmental impact of abandoned coal mines in Natal, South Africa.

Abandoned coal waste dumps and leaking coal mines generate large quantities of acid mine drainage which, when it drains into creeks and rivers, destroys the benthic environment and renders the water useless for stock grazing and even irrigation.

Historically, coal mine waste usually was deposited in lower-lying ground, invariably alongside a creek or in the path of runoff drainages. The result is that the sides of culm banks would be eroded allowing air and water to penetrate, thereby speeding up the oxidation process.

Areas affected by acid mine drainage were invariably characterized by dead trees and denuded vegetation.

In recent times, since expense and attention has been paid to preventing AMD where possible and treating that which cannot be prevented, there has been a marked improvement in the environment around coal mines and in the quality of streams draining from coal mining districts. AMD remains an expensive problem that needs a less expensive, permanent solution.

ACID MINE DRAINAGE - GOLD AND BASE METAL MINING, COLORADO

There is a highly mineralized belt extending through the Rocky Mountains from Jamestown, Colorado, to Cripple Creek, and on to Telluride. It includes such gold mining districts as Georgetown, Idaho Springs, Central City, Victor, and a host of additional abandoned or forgotten sites.

The famous Argo Tunnel and Yak Tunnels were driven as drainages to allow access to mineral deposits. These tunnels today still serve to drain water from these areas.

Base metal and gold mining of the past has left scattered wasterock piles on the sides of the mountains, mazes of tunnels which serve to collect and drain seepage as well as conduits for air into the mineralized areas, and tailings piles generally on the valley floors, often alongside creeks. The wasterock and tailings clearly are rich in oxidizing sulfides. The abandoned workings and drainage tunnels drain large underground areas which were not regarded as ore, but which nonetheless contain high percentages of acid-generating sulfide minerals.

The ownership and responsibility for these sites has, in most cases, long ago passed from the people who operated these small workings. The responsibility for protecting the environment from damage by these sites now has fallen to the state:

COLORADO DEPT. OF NATURAL
RESOURCES

J. David Holm

HOLM and SIMPSON (1981) reviewed acid mine drainage from the ARGO Mine Tunnel because it is, in their words, one of the most dramatic examples of acid mine drainage in Colorado. The Argo Tunnel drainage is the largest single source of trace elements in the Clear Creek watershed which serves as an important industrial and municipal water supply for the Denver metropolitan area. Their paper is included in the chapter on acid mine drainage treatment.

The mines of Clear Creek and Gilpin were famous, but so were many of the problems in mining these areas. Water seeped into the workings so that pumps worked 24 hours a day. The idea of tunneling into a mountain to reach ore on a slightly inclined plane was applied as a means of draining water and transporting men and equipment at many locations since the 1870's, and the Argo Tunnel was one of the few that succeeded. By 1898, Samuel Newhouse's Argo Tunnel had reached a length of 7,000 feet towards Central City and had intersected 200 mines and over 1,140 veins. By 1904, the tunnel was 12,000 feet long and served many mines producing gold, silver, lead, copper, and iron sulfides. Production of precious metals served by the Argo Tunnel is estimated to have totalled more than $100 million at old values. By 1910, the tunnel was completed at a length of 21,896 feet where it connected to Central City. On January 19, 1943, an underground aquifer was penetrated at one of the workings with the result that the Argo Tunnel was flooded and the tunnel closed.

During the past 25 years, there have been several "blow outs" of toxic mine water. These voluminous releases of polluted water are believed to be caused by roof collapses in the tunnel which prevent water from draining normally. Water backs up behind these dams, and tremendous hydrostatic pressure can develop. On May 21, 1980, a near catastrophic release of toxic water occurred which resulted in the temporary shutdown of five downstream municipal and industrial intakes. Clear Creek water quality was severely impacted throughout the entire downstream reach of 35 miles to the confluence with the South Platte River.

U.S. GEOLOGICAL SURVEY MINE DRAINAGE STUDY (1977)
ARGO MINE DRAINAGE

	Mean Concentration (mg/l)	Proposed Water Quality Standard (mg/l)
TDS	2,925	No Standard
pH	3	5.5-9.0
$SO_4^=$	1,951	250
Arsenic	127	0.05
Cadmium	0.152	0.002
Copper	5.92	0.06
Iron	186.5	1.55 (Total)
Lead	0.14	0.009
Manganese	93.6	1.1 (Total)
Silver	0.028	0.0001
Zinc	46.3	0.55
Nickel	0.39	0.05

The Argo Tunnel water quality reflects one of the impacts of mining on the environment and on water quality.

In the Colorado Rockies, there are numerous larger mines that are still operating and which have a serious impact on water quality. These include the Gilman Mine and Gilman Tailings alongside the Eagle River not far from Vail, Colorado. The Gilman Mine is discussed in a trip report in Appendix I. Gilman tailings, along with the Argo Tunnel, are now designated as Superfund sites under CERCLA regulations as targets for expensive mitigating measures. There are six Superfund sites in Colorado alone, all mining and mineral processing sites which are having an impact on water quality. The others include ASARCO's operations at Leadville which drain into the Leadville tunnel, ASARCO's Globe smelter in Denver, and the COTTER CORPORATION's old uranium millsite at Canon City where contaminated seepage from uranium ore stockpile areas is migrating towards a municipal reservoir. NEWMONT MINING's Idarado mine-mill site is also named as a Superfund site where hexavalent chromium used as a flotation reagent has seeped from tailings into the local aquifer which serves wells in the Telluride, Colorado, area.

At Crested Butte, Colorado, AMAX, INC. has spent $12-14 million on water treatment facilities and site stabilization of the old Keystone Zinc Mine and tailings. Operation of this treatment facility costs around $700,000 per year. The Keystone mine and mill is just one of many in the Colorado Rockies which generates acid mine drainage, but it is one of the few where acid mine drainage is treated. It would be an interesting calculation to determine the DCF ROI over the life of the Keystone Mine if the reclamation and water treatment capital and operating costs were to be included.

In North American operations, chloride may often not be a serious environmental problem, and it is seldom regulated. However, where solutions have to be recycled or where water is used for pressure oxidation or leaching processes in stainless steel vessels, chloride in the water can have expensive consequences. Also, water from the lower reaches of the Colorado River will soon have to be desalinated using an expensive reverse Osmosis process. Discharge of chloride and sulfate-containing effluents into the Colorado River may logically become restricted in the future.

There are also new approaches to hydrometallurgical treatment of ores and concentrates that are under development including ferric chloride leaching processes, ammoniated leaching, and others.

Most recently, hydrometallurgical processing of refractory gold ores, including biological and pressure oxidation of sulfides, are gaining favor over roasting. These hydrometallurgical and biological oxidation processes also generate acid and cause

unwanted metals to dissolve. Recent process arrangements employing pressure oxidation allow the dissolved metals to be separated for simpler treatment before they come into contact with cyanide for gold leaching, which would complicate the metal removal process in effluent treatment. The new McLaughlin project of the HOMESTAKE MINING CO. in California is able to wash most of these nuisance metals from the oxidized ore before cyanidation.

In hydrometallurgical leaching of copper and zinc concentrates (with and without roasting), jarosite salts are generated which must be disposed of. Usually, the jarosites are stored in ponds. Seepage from jarosite ponds is a potential source of contamination and is a recognized environmental challenge. The more expensive "hematite process" has been developed for use in parts of the world where there is inadequate space for jarosite containment ponds around zinc and copper hydrometallurgical refineries.

MINE DRAINAGE - NEVADA

The abandoned mine pit at the famous Getchells Mine in Nevada until recently was partially filled with 400-600 million gallons of water at a pH of over 7. Although this is not an example of acid mine drainage, it is certainly an example of mine drainage. The water contained about 2,000 ppm TDS, mainly $CaSO_4$, which exceeded allowable limits for direct discharge to the natural drainage in Humbolt County, Nevada. This water would, if discharged to the natural drainage, end up in a lake. Deep well injections were examined and estimated to cost around $2.5-3.0 million. A second, probably more practical alternative being explored in 1984 was the possibility of using the water for crop irrigation--e.g., for alfalfa. It is believed that even though the water in the pit was high in TDS and may have also contained some dissolved metals, it probably, in its desert environment, was not causing damage to the environment.

Nevada is a very dry state, and evaporation exceeds precipitation. Consequently, mine-mill operations can almost always operate on a zero discharge basis. A new gold or silver mine in Nevada can invariably design for solution recycle, thereby avoiding the need for effluent discharge. If a barren bleed is necessary, then this can also be achieved without discharge of an effluent by simply evaporating excess water.

Occasionally, the water balance at Nevada operations may be upset by snowmelt or torrential downpours. In such cases, excess solution would unavoidably be released to the environment. Because of large seasonal differences in the precipitation/evaporation ratio, it is important to design solution impoundments in such a way that there is always adequate capacity to store water that can drain from heaps in heap leaching operations.

Nevada is a very dry state, and one would have expected that good quality water would be extremely valuable. Yet, there are mining operations that use huge quantities of

water in gold recovery by CIP on a once through basis with no recycling at all. In one case, water is simply pumped with tailings to the desert floor where it seeps into groundwater. No data was found as to the quality of water in the aquifer that is impacted. This practice does seem to be a waste of water and to have potential for groundwater damage of the kind that is now being scrutinized by regulatory authorities. Fortunately, this approach is not typical in the industry as more companies realize the benefits of being self-policing. It is bad examples such as this, however, that provide fuel to the regulatory agencies, however.

ACID MINE DRAINAGE: ABANDONED MINE SITES IN CALIFORNIA

Sulfur Bank Mine

In California, there are several areas where mining activity of the past is believed to still have an impact on water quality. One such case is the Sulfur Bank Mine.

The Sulfur Bank Mine belongs to the Bradley Mining Company of San Francisco. It is located on the Oaks Arm of Clear Lake in Lake County, California. The water runoff from the abandoned mine area is believed to be the source of mercury which has reached a level of 0.25 ppm Hg in Clear Lake. The mercury level in some fish caught in the lake is well in excess of 1 ppm, and about 75% of the fish in the Lake exceed this level. The larger the bass, the higher their mercury level.

The water discharged from the mine is acid, and discharge is seasonal, reaching a minimum in the summer.

Walker Mine

The Walker Mine in Plumas County, California, is located 150-200 miles north of Sacramento at an altitude of 6,000 AMSL. The nearest towns are Quincy and Portola, California.

The Walker Mine operated since the 1800's and was abandoned in the 1940's. Acid mine drainage at pH 4 containing 18 ppm copper, some zinc, and some sulfate drains from this mine at a rate of 300 U.S. gpm to 2,000 gpm.

At its 6,000 foot altitude, the mine is not accessible in winter because of snowcover. The acid drainage flows yearround into the Grizzly Creek and India Creek on the east branch of the Feather River. The mine is said to involve extensive underground workings into three orebodies. A firm of consultants was hired and, after $260,000 worth of study and pilot testing, they seem to be busy reinventing the wheel.

The minesite also includes a large tailings area, but it is not clear whether these tailings are also generating acid mine drainage.

Possibly, additional information on the site can be obtained through the appropriate California Regional Water Quality Control Board or the consultants:

PEARSON, POTTER AND ASSOCIATES
Richmond, CA

The Penn Mine

The Penn Mine is a third known abandoned copper mine in California that has resulted in AMD discharge over many years. This one is under the jurisdiction of the Bay Area Municipal District, Oakland, California, who would be able to provide details. This mine is located one and one half hours by car southeast of Sacramento in the drainage area serving the Comanche Reservoir. AMD from the site has caused damage to the Mokelumne River and wiped out a trout hatchery. To date, $500,000 has been spent on collecting this drainage and keeping it out of the reservoir.

The perpetual and persistant existence of acid mine drainage pollutants of surface waters from old abandoned mine sites within the areas under their jurisdiction is a motivating force in the critical attitude shown by regulators toward proposed new mining operations in their areas.

ACID MINE DRAINAGE - WISCONSIN ZINC DISTRICT

HOFFMANN (1984) presented an interesting account of the Shuilsburg, Wisconsin, zinc mining district where for many years the Eagle-Picher Mining Company mined zinc ore from mines that were dewatered by pumping. When the mines were worked out, however, and the old workings were allowed to flood, the quality of water in the regional aquifer in the vicinity deteriorated rapidly making it unfit for its traditional applications, namely livestock watering and human consumption. The interesting aspect here is that groundwater quality was impacted only after the mining operations stopped, and the company had moved away. The nature of the contamination was mainly high magnesium and sulfate levels in the water.

REAGENTS USED IN MINING AND MINERAL PROCESSING

A wide range of reagents are used in mineral processing and metallurgical treatment of ores and concentrates. These range from: strong acids for the leaching of ores or elution of ion exchange resins, ammonia, SO_2, and NaOH used in conditioning of pulps prior to flotation; Na_2CO_3 for alkaline leaching of uranium; flotation reagents, including glycols, xanthates, thiophosphates, etc.; organic solvent extraction agents;

hexametaphosphate scale inhibitors; polyelectrolyte surfactants, coagulants, and flocculants; hydraulic fluids; greases; oil; lime, etc. One of the best reviews on the use characteristics and toxicity of mine-mill reagents has been compiled by HAWLEY (1977).

JOHN R. HAWLEY
Head, Mining, Metallurgy and Inorganic
Chemistry Unit
Quality Protection Section
Water Resources Branch
Ontario Ministry of the Environment
1-4 St. Clair Avenue West
Toronto, Ontario

The toxicity of a wide range of bulk chemicals and acids, frothers, collectors, xanthates, pH modifiers, activating agents, depressing agents, dispersants, flocculants, coagulants, coagulant aids, lubricants, and explosives is discussed in a 250-page document. He also reviews biodegradability of mine-mill reagents and tailings area design and its relationship to the toxicity and biodegradability of mine-mill reagents.

The chemicals themselves tend to be relatively expensive and, as such, the mining industry uses these chemicals with as little waste as possible. However, even a small mining operation may use several hundred pounds of an essential chemical during a normal working day. Residual qualtities of many of these compounds can and do escape in effluents to receiving waters. Also, accidental chemical spills can and do occur. HAWLEY (1977)'s report is the first that deals with the toxicity of these numerous chemicals on aquatic life and on water quality. Numerous references are cited. He emphasized that the reliability of the data is largely questionable, and that it is useful as a guide to the relative toxicities of various mine-mill reagents. The following general conclusions are worthy of note:

1. Mine-mill reagents vary in toxicity. Some are highly toxic while others, considering the circumstances of use, are relatively non-toxic. Some are persistent and hence will escape from a tailings area. Others are unstable and will break down in a tailings area.

   Obviously, when reagents are being chosen for use in a mine-mill circuit, the least toxic compounds available should be chosen. Included in the definition of "least" toxic compounds are those which break down rapidly into innocous substances in a waste stream or those toxic substances which can be removed easily from a waste stream using conventional waste treatment technology.

2. The toxicity of many contaminants under field conditions and in mine/mill effluents, which contain several ionic species, is not wellknown for many contaminants and is often very much different from that determined on simpler systems in the laboratory with unacclimated species.

3. The use of mine-mill reagents that are persistent (that is reagents that do not break down in a natural environment) should be avoided if possible.

4. The use of mine-mill reagents having known or suspected nutrient properties should be avoided if possible.

5. When choosing a reagent for use in a mine-mill circuit or process, the total effect of that particular reagent on the receiving waters should be considered. Reagent characteristics to investigate would generally include chemical oxygen demand, biological oxygen demand, biodegradability, effects on local aquatic life (plant and animal), and the effects on total dissolved solids concentration and the hardness of the receiving stream.

6. The use of mine-mill reagents that consist of or contain water soluble metal salts that are known to cause undesirable environmental effects should be avoided if possible.

In some cases, such as uranium extraction plants in the Elliot Lake region of Ontario, mill capacities range from 3,000 to 6,000 tons of ore per day. About 65-70 pounds of 100% sulfuric acid is used per ton of ore treated. In tests, surprisingly low levels of H_2SO_4 were found to be toxic to fish. For example, BELDING (1927) reported that only 6.25 mg/l H_2SO_4 is toxic to trout in 24 hours. However, it is noted that a dose that would be lethal in distilled or soft water might be harmless in a highly buffered water.

Surprisingly, just 92 mg/l lime in water was reported by MEINCK, et al. (1956) to be toxic to trout after 26 minutes of exposure.

Ammonia is used in large quantities as a pH modifier and also for precipitation of uranium. HAWLEY (1977) reports that nearly all mine-mill operations in the province of Ontario utilize ammonium-based compounds for one reason or another, including ammonium-based explosives. The toxicity of ammonia and ammonium salts to aquatic animals is directly related to the amount of undissociated ammonium hydroxide in solution which, in turn, is a function of pH. A high ammonia level at a low pH may not be toxic but if the pH is raised, toxicity is also increased. The toxicity of a given concentration of ammonium toward fish was found to increase by 200 percent between pH 7.4 and 8.0. Carbon dioxide at 15-60 mg/l appears to reduce the toxicity of ammonia in water by reducing the pH.

Hexavalent chromium has traditionally been employed as a galena depressant in the separation of copper-lead sulfide flotation concentrates. Hexavalent chromium remains soluble in water over a wide range of pH unless it is converted to trivalent chromium in which case, it precipitates above pH 5. Hexavalent chromium is very toxic and also is undesirable in domestic water supplies. This is the subject of a Superfund site at the Idarado Mine near Telluride, Colorado, where hexavalent chromium was used as a flotation

reagent for a short period. The state of Colorado and others are preparing to sue the mine owners under the CERCLA (Superfund) regulations for many tens of millions of dollars in compensatory and reparation damages, even though no specific incidences of actual damage to life or property have been reported.

The occurrence of hexavalent chromium in groundwater near Telluride was identified and described by the U.S. Geological Survey and reported by GROVE, et al. (1979) and STOLLENWERK and GROVE (1979).

METALLURGICAL PROCESS SOLUTION EFFLUENTS

Hydrometallurgy

Hydrometallurgical processes employ corrosive reagents as lixiviants and oxidants to leach metal values from ores. For example, sulfuric acid is commonly used to leach uranium, copper, and zinc from oxide ores and from roasted copper concentrate calcines as well as zinc concentrate calcines.

Cyanide solutions at pH 10-10.5 are used to leach gold and silver from ores. In hydrometallurgical processes, metals other than those which are to be recovered as products and by-products can also be leached. For example, in leaching Witwatersrand gold ores, small amounts of cobalt, nickel, copper, and others are also dissolved. In North American gold hydrometallurgy, small amounts of arsenic, copper, lead, zinc, nickel, antimony, mercury, thallium, and others may be leached depending on the ore being treated.

In the hydrometallurgical processing of ores and concentrates, the environmental effects of the lixiviants used and also contaminants leached from the ore in the process need to be taken into account. In gold and silver leaching, cyanide solutions are recycled until such impurities build up to such levels that they interfere with the process. To keep the process working, a barren bleed is necessary. This bleed contains cyanide complexes of a wide variety of metals.

In leaching uranium ores, oxidants such as manganese dioxide and sodium chlorate are routinely used to make the reaction work. These add manganese and chloride to the pulp solution.

Flotation

In flotation processes, a whole range of reagents are used for adjustment of pH and conditioning of mineral surfaces, collectors, frothers, depressants, activators, etc. These reagents may react with mineral species in the ore or with eachother. For

example, SO_2 used to condition complex ores in an alkaline medium generates thiosalts. Thiosulfate is also generated when some sulfide ores are milled in an alkaline medium. Oxidation of sulfides during milling and, commonly, dissolution of metal values from oxidized fragments of ore can result in metal buildup in recirculated flotation mill solutions.

At the PALABORA MINING COMPANY, South Africa, flotation plant solutions build up calcium and magnesium from the carbonatite ore. These species interfere with the process and must be counteracted by gangue depressent addition. After recovery of copper from the ore at PMC, their tailings are pumped across the fence to Foskor for phosphate mineral recovery. The quality of entrained water in the tailings contains several dissolved species as a result of contact with the ore, including relatively high levels of fluoride.

Several organic reagents may be added as reagents in flotation recovery operations. Organic species in mining and metallurgical effluents are not generally regulated (except visible oil and grease). WIXSON (1977) described a multi-disciplinary intensive study of environmental pollution at the New Lead Belt of southeastern Missouri and found considerable amounts of organic contaminants in the tailings decant effluents from both mine-mill operations in the area.

Pyrometallurgical Processes

Pyrometallurgical processes employ roasting and smelting as a means of extracting, separating, and refining metals. These originally were dry processes until the need to prevent air pollution arose. Since then, water has been used to scrub SO_2 from roaster gases, generally producing sulfuric acid, and in smelter and refinery operations to remove airborne particulates. Ambient air in lead refineries is extracted and cleaned to provide hygienic working conditions. The scrubber sludges produced can build up large amounts of metal values, typically containing arsenic, lead, copper, cadmium, zinc, nickel, cobalt, etc.

Cleaning roaster gases and smelter off gases prevents the distribution of metal-bearing particles to the environment around the metallurgical complex environment. This results in a much reduced water quality control problem since less soluble metals are now distributed and not as fallout where they can come into contact with plant runoff water or across the general environment.

EFFLUENTS

Consequently, just about every metallurgical process yields a solution containing reagents, metal contaminants, or process-generated chemicals. In many cases, these solutions can be treated and recycled resulting in a zero discharge operation. In others, this is not possible and a bleed is necessary, or it is necessary to discharge an effluent to maintain a water balance in the plant.

In some cases, a zero discharge mill operation may be feasible, but mine drainage water containing contaminants is used in the mill as a way of treating it. This additional water imput to the mill requires that water be discharged as an effluent from the mill tailings system even in areas where there is net evaporation.

Comprehensive information surveys on the toxicity effects of a huge list of contaminant species that can be found in metallurgical process effluents have been compiled by several organizations including ONTARIO (1979), U.S. EPA (1972, 1976,), and Environment Canada Reviews of Water Quality Criteria for many contaminant species, e.g., arsenic, lead, and copper which are referenced in the sections of this report that deal with the individual contaminants.

ORGANICS - LUBRICATING OIL, DIESEL, GREASE, HYDRAULIC FLUID

Mining operations consume significant amounts of lubricating oil, diesel fuel, grease, and hydraulic fluids.

Available information, according to ONTARIO (1979) on occupational health and industrial hygiene, indicates that tolerable health concentrations for petroleum-derived substances far exceeds the limits of taste and odor. Hazards to humans from drinking oil-polluted water will not arise because such substances become objectionable at concentrations far below their chronic toxicity levels. Oils of animal or vegetable origins are usually non-toxic to humans and aquatic life.

The amount of oil that produces a visible oil slick varies depending on the type of oil and weather conditions. The American Petroleum Institute estimates that the first trace of irridescence or color is formed when about 15 ml of oil is spread over 100 m^2, i.e., 100 U.S. gallons per square mile (0.15 microns thick), (NAS/NAE, 1974).

ONTARIO (1979) lists four objectives for oil and petrochemicals in water.

Oil or petrochemicals should not be present in concentrations that:

- Can be detected as a visible film or surface discoloration.

- Can be detected by odor.
- Can cause tainting of edible aquatic organisms.
- Can form deposits on shorelines or bottom sediments.

Surface slicks must be prevented to protect water birds and aquatic animals. Even less obvious but long sustained small slicks such as from sewered oil will have debilitating effects on resident water birds in the end. Heavy oil contamination causes rapid death.

In general, oil and other petrochemical contamination of water by mine-mill operations is a lesser evil than AMD. Once a mining operations ceases, the source of these materials to the environment ceases, and the problem will be solved. Oils and petrochemical products can cause problems in metallurgical processes when contaminated water is recycled.

The introduction of this type of material into mine/mill effluents from operating mines is much more widespread than is generally realized and has a lot to do with underground housekeeping practices and on whether the local garage owner has access to the dump as a location at which to dump waste crankcase oil.

In the water treatment plant at AMAX's Mount Emmons project, operations underground invariably introduce hydraulic oil into the system. This oil must be removed from the surface to avoid coating the pH meter bulb and causing an erroneous reading which would also cause inaccurate activation of the automated reagent adjustment in the pH control system.

ONTARIO (1979) applied an application factor of 0.09 to the average lethal concentrations of oils for freshwater fish and concluded that the following are "safe" levels for fish:

Bunker Oil	180 ml/l
Used Crankcase Oil	120 ml/l
Crude Oil Slicks	45 ml/l
Jet Aviation Fuel	45 ml/l
Diesel Fuel	15 ml/l
Automobile Diesel	9 ml/l

SUSPENDED SOLIDS

Fisheries, particularly salmon spawning grounds, are particularly sensitive to suspended solids. In Idaho at the headwaters of the Salmon River, a famous sport fishing ground and tourist attraction, the Stibnite Mine heap leaching operation is located right on the banks of a creek. Although the Forest Service is concerned about the possibility of cyanide release into this creek, they are even more concerned about suspended solids

from the mining/extraction operation washing into this salmon spawning ground at the wrong time of the year.

A nearby small placer operation, the Golden Reef Mine, incurred a small spill containing suspended solids which involved a stream in the Payette National Forest on Thunder Mountain. This resulted in a settlement with the Idaho Dept. of Health and Welfare and the Idaho Dept. of Lands in which the company was fined $5,000 and $20,000 for damage to the streams. This led to a congressional inquiry in the U.S. Congress led by Representative John Sieberling, D-Ohio, into the incident and involvement by the Idaho Conservation League. Clearly, effluents containing suspended solids are harmful to both fish, regulators, and the emotional wellbeing of certain congressmen, as well as being inflamatory to environmental groups.

ONTARIO (1979) found that suspended solids should not be added to surface water in concentrations that will change the natural Secchi disk reading by more than ten percent. The turbidity of water can have a great effect on the types and quantities of algae that grow in lakes by altering the quantity and quality of light available for photosynthesis as shown by BRYLINSKY and MANN (1973) and several other authors.

CHANDLER (1940, 1945) showed that the algal productivity is high in the Great Lakes when turbidity is low and vice versa. His studies also show that the composition, size, duration, and emergence of phytoplankton pulses in the Great Lakes are influenced by turbidity (CHANDLER, 1942a, 1942b, 1944, 1945).

The U.S. EPA in a report published in 1975 adopted recommendations of the NAS/NAE (1974):

"Aquatic communities should be protected if the following maximum concentrations of suspended solids exist:

High Level of Protection	25 mg/l
Moderate Protection	80 mg/l
Low Level of Protection	400 mg/l
Very Low Level of Protection	+400 mg/l

EIFAC (1966) identified four categories of concern in the effect of suspended solids on fish, namely:

1) Direct action on fish either killing them or reducing their growth rate, resistance to disease, etc.

2) Preventing successful development of fish eggs and larvae.

3) Modification of natural movements and migrations of fish.

4) Reducing the abundance of food available to fish.

This investigation concludes that turbidity and suspended solids content of water are not synonymous. Suspended solids load can change the productivity and behavoir of fish in a lake and/or creek and certainly will activate the behavioral instincts of private environmental groups, regulators, and congressmen, mainly because of the aesthetic obviousness of this type of pollution.

TEMPERATURE

Trout, one of the symbols of a clean environment, for example, do not survive in streams or lakes where the water temperature exceeds a certain maximum. That is why trout occur in mountain streams rather than subtropical ponds.

At ST. JOE MINERALS CORP.'s operation at Pierrepont, New York, for example, the company has installed an innovative meander system in which plant and algal growth is encouraged as a means of enhancing natural biological water purification processes. In order to provide a viable environment for marsh plants, these ponds can be no deeper than about three feet. While the marsh was establishing itself, an unexpected problem arose. During summer days, the temperature of water in the effluent from the meander system (before the marsh vegetation was fully established) exceeded that of the minewater entering the pond and also exceeded limits considered safe for the survival of trout in the small receiving stream. Presumably, trout would migrate downstream and upstream of the discharge point temporarily during the days when they find the temperature unpleasant.

Minewater from some mines is likely to be warm or even quite hot, and the temperature effect on receiving streams should be taken into account when considering the environmental impact of minewater discharge.

SOME TECHNOLOGIES THAT REDUCE WATER CONTAMINATION

MINING METHODS AND BACKFILL TECHNOLOGY

Mining methods have evolved within recent years which will have a beneficial impact on the environment and greatly reduce the impact on water quality as well as long-term control requirements after the mine-mill complex has shut down. A very important part of this is the development of mine backfill technology.

Mine backfill technology, as well as mining methods which depend on backfill for their success, are already well developed in Canada, particularly in the exploitation of massive sulfide deposits.

Waste rock and/or tailings are returned underground to fill the voids left by mining. From a water quality point of view, this achieves two important objectives. First, the cavity is filled thereby eliminating space for minewater to accumulate or circulate as well as for air to circulate in the old stopes. Second, the volume of tailings and wasterock left above ground is reduced correspondingly, thereby leaving less above ground as a potential AMD generator.

There are limitations to backfill application, however. First, due to the expansion factor when rock is crushed and milled, not all the material can be replaced back in the mine. At least 40% would still have to be disposed of in the conventional way. Second, very high sulfide tailings are pyrophoric and cannot be used as backfill as this results in a fire hazard underground. Hence, that fraction of the tailings which are the cause of the greatest environmental concern cannot be disposed of in this way.

On the Witwatersrand, underground disposal of tailings is already practiced on a growing scale at this time by some of the companies. It is believed that the ANGLO AMERICAN CORPORATION of South Africa may be taking a lead.

KIDD CREEK MINES primarily employs sublevel blasthole stoping for underground mining operations. During pillar recovery in the No. 1 Mine and panel mining in the No. 2 mine, the free-standing fill exposures may reach a height of 100 m or more. Consequently, a competent consolidated rockfill has been required to fill the mine openings. The successful technique of backfilling these stopes that has been developed for KIDD CREEK MINES has been described by YU and COUNTER (1983). More information could be requested from:

TAILINGS DISPOSAL TECHNOLOGY

New technology for tailings disposal can dramatically reduce their impact on the environment and reduce concerns about their long-term stability. Two important aspects are of particular interest here. First is the "sub-aerial" tailings disposal method first used in South Africa which, depending on the nature of the tailings material, can make such an impermeable tailing that it acts to effectively encapsulate contaminants. Second

is the "controlled release" tailings dam design in which dewatering trenches are constructed inside the tailings pond to remove liquids from the impoundment. This lowers the phreatic pressure on the dam wall thereby rendering it safer and more stable. It also allows seepage from the tailings dam to be directed to one outlet from where it can be monitored, discharged, treated, recycled to the plant, or returned to the dam. In both cases, the major benefit of the new technologies is improved positive control of the way the tailings impact the environment.

An important example of sub-aerial tailings disposal which allows stabilization by encapsulation of a water treatment sludge that would otherwise be toxic is THE KEY LAKE MINING operation in Saskatchewan. This approach is also applied on numerous Witwatersrand slimes dams.

The Climax Molybdenum Division of AMAX operation at Climax, Colorado, is the classic application of the controlled release technique of tailings disposal using underdrains. AMAX staff, in fact, refer to this as the "Climax System" which they developed.

An engineer who was involved in the development and implementation of the controlled release tailings system at Climax and who new offers an independent consulting service is:

TAILINGS RETREATMENT

On the Witwatersrand, the retreatment of sand dumps is undertaken on a massive scale by several companies. This has several beneficial effects on the environment, particularly on runoff and groundwater quality.

1) The removal of pyrite from the tailings by flotation reduces the acid generating capacity of the tailings.

2) Recovery of soluble uranium by acid digestion removes uranium values that may already have been solubilized in the heaps due to the action of acid generated by pyrite oxidation in situ.

3) Fine grinding of tailings for retreatment is not often practiced because the grade is too low to justify the expense. Some operations apply a sand/slime split. The slime fraction can now be disposed of using the less permeable "semi-dry" tailings disposal technique referred to above which makes a less permeable tailing.

4) The new tailings can be designed using the latest, more environmentally conscious designs and can sometimes also be moved to a less sensitive location. For example, the Simmergo tailings, after reprocessing, are being pumped 38 km to the new ERGO/E. Daggafontein tailings pond south of Brakpan.

IMPOUNDMENT TECHNOLOGY

Impoundment technology has advanced significantly in the last few years. Not only have a host of new, improved synthetic membranes come onto the market, but the knowledge of how to apply them has advanced to a point where the risk of failure can be significantly reduced. As importantly, geotechnology has developed to a point where it is possible often to find a site where a liner is not needed at all.

Building a pond which is lined with a synthetic membrane is not nearly as easy as it looks, and there have been numerous failures, even of those ponds designed by large, stable, high-profile companies.

New bentonite-stabilized sand lining technology appears to be particularly effective and in some locations, potentially economical as applied at the GETTY MERCUR Mine at Toelle, Utah, and as a safety measure beneath a synthetic membrane at the KEY LAKE MINES operation in Saskatchewan.

In South Africa a treated bentonite lining, in which the clay is spread out as a layer without being mixed into the soil, is finding numerous applications.

WATER TREATMENT

Effluent treatment encompassing a huge spectrum of applications and technologies is increasingly required to meet effluent discharge permit requirements. Several of these technologies are described and discussed in chapters 12-53. It is always advisable to try and find a way through creative water management to prevent or to solve a water quality problem without the need for a water treatment plant.

WATER MANAGEMENT ADVANCES

Water management advances make it possible to use less water and, through appropriate and informed recycling, to reduce the volume of water that is impacted by the operation and the process.

A very important aspect of areas where there is a net precipitation is to design an operational area that reduces, as much as possible, the catchment area that will collect precipitation. Once water drains into this catchment area and comingles with other contaminated waters draining from the plantsite or tailings area, it will all need to be treated. Keeping the catchment area as small as possible by building interceptor trenches, berms, etc. reduces the size of this catchment area and can, therefore, result in the need for a much smaller water treatment plant or evaporation pond.

Examples of operations where water management has included the use of measures to reduce the catchment area of runoff water are many and include the following:

AMAX: Mount Emmons Water Treatment Project
AMAX: Climax, Colorado, Tailings
HOMESTAKE McLaughlin Project, Knoxville, California
NORANDA Grey Eagle Gold Operation, Happy Camp, California

The first three of these operations are described in trip reports in Appendix I.

CONCLUSIONS

1) It is concluded that the impact of mining and metallurgical operations on the environment and on water quality may be blatant and severe, or it may be subtle and gentle.

2) At the Friedensville Mine in Pennsylvania, a case was found where minewater was so clean and contained so little nutrient value that it could not support a lively aquatic

ecology (e.g., trout) until the mining company (THE NEW JERSEY ZINC COMPANY) added nutrients to the minewater discharge (BAKER, 1984).

3) Some environmental impacts of mining are temporary and persist only as long as the mine is in operation--typical mine life is 10-20 years before reserves are depleted. Examples of such temporary impact would be the impact of reagents which are added only during the life of the operations.

4) Some environmental impacts of mining may persist for several centuries after a mine shuts down. Examples are acid mine drainage from inclined drainage tunnels and sulfide tailings oxidation from a wide variety of mining categores.

5) Some environmental impacts are readily remediable, e.g., pH adjust, while others are not. Right now, there is no known way to dispose of highly sulfidic mine-mill tailings and wasterock at mines located far from the coast or deep lakes in net precipitation climates that avoids the need for perpetual AMD treatment and tailings management.

6) In arid climatic regions where effluent can be impounded and evaporated and where there is less likely to be valuable fishery resources and aquatic ecologies to protect, the impact of intelligently designed mining and milling operations on the environment is much easier to control than in areas where there is a net precipitation, and discharge of effluents cannot be avoided.

7) In considering the environmental impact of mining and milling operations, there are three phases to be aware of:

   - During construction and startup and early operation of the mine/mill.

   - Mature operation impact, i.e., after the tailings in the pond and wasterock have a chance to oxidize.

   - After mine/mill closure.

8) The impact on the environment of historical mining operations is not a perfect model of what to expect from current and future operations. The modern mines tend to be larger and to disturb more rock and land. Because of recent environmental awareness and pressures and changes in design and philosophy, mining and milling operation designs now take water quality and the environment into account. Much more emphasis is placed on water conservation and recycling and on advance planning for ultimate mine-mill closure.

CHAPTER 2

OBJECTIVES AND SCOPE OF WATER MANAGEMENT

Focus on the need for environmental and water quality protection that emerged in the U.S.A. and which is spreading to other industry centers such as South Africa and Australia and now to the third world make it imperative, or at least very desirable in most cases, to develop a quantitative water management plan before a mine/mill operation is started and also to have an active water management program.

The cost of impoundments is high and by managing an operations water balance, it is usually possible to reduce the size of impoundments needed to take care of an operation's fresh water requirements, recycle solution inventory, and effluent control. It may however be better to spend more up front to save bigger problems after mine closure. Remember to manage the root of the problem, not just the symptoms.

OBJECTIVES OF WATER MANAGEMENT

1. To insure adequate water to meet the operation's needs during the dry season.

2. To avoid or minimize the volume of effluent that must be discharged or treated.

3. To avoid accidential spills due to impoundment failure and/or overflow, particularly during the months of spring runoff and/or highest precipitation.

4. To optimize water utilization to achieve the most cost effective combination of water treatment facilities, water recycling and reuse, and evaporation and effluent discharge within the constraint of minimized negative impact on metallurgical recovery efficiency.

5. To manage the seggregation of water and process solutions in various parts of an operation as needed for process and/or environmental reasons.

6. Because acid mine drainage is such an important problem, an objective of water management must be to resolve the problem of acid mine drainage in mines and tailings disposal sites.

WATER MANAGEMENT - A SYSTEMS APPROACH

This section of the report may not provide details of as many technologies as some of the other chapters, but it contains the most important message. A few companies already use

a systems approach to water management and treatment, and these include some of the sponsors of this study. Many mining companies are structured in such a way that implementing a systems approach is not easy. The systems approach has already proven very successful in cutting water consumption in more than one drought-stricken mining center, and in capital cost savings in new mine-mill complexes in wet areas.

WHAT IS A SYSTEMS APPROACH?

The systems approach examines every aspect of the mine-mill-tailings-wasterock system to design an optimized use and management of water within the framework of the overall economics of the operation.

Because water is used and affected by each unit operation and even by the nature of the climate, topography, soil and rock type, and vegetation as well, it is necessary to take the complete picture into account. This systems approach to water management is best applied before the mine or mine-mill system is installed. However, because it is a relatively new concept as far as water management is concerned, there are many more cases of significant cost savings through the application of a systems approach to existing installations.

The aims of a systems approach are:

1) To use one water problem to solve another through synergisms to achieve the best overall cost benefit.

2) To use the assets of the operation to advantage, e.g., large tailings pond or bog.

3) To avoid the need for costly treatment where possible--prevention is better than cure.

4) To take long-term costs into account; final reclamation should be included in the original plan, including consideration of long-term acid mine drainage inhibition or control.

5) To integrate incremental metal recovery or reduced metallurgical efficiency into water management considerations.

6) These days, public relations aspects may also be included.

HOW TO APPLY A SYSTEMS APPROACH

In many of the larger mining companies, water management is the responsibility of the mechanical and engineering department which reflects the days when pipes and pumps were the main concern about water.

Implementation of a systems approach in water management whatever the prime goal, be it conserving water or meeting effluent discharge regulations in the most cost effective way, requires that all the specialized disciplines and expertise on a mine-mill complex be taken into account. In several cases, local municipal effluents and wastes have been incorporated into the system or synergisms found between two or more adjoining mining operations. These disciplines include:

Geology	
Mining Engineer	- Design of a Mine
Mining People	- Mining Operation
Metallurgical Engineer	- Design of Mill and Process
Mill Operating People	- Mill Operation
Environmental Engineer	- Tailings Disposal
	- Effluent Treatment Facilities
	- Monitoring
Biologist-Botanist	- Passive Water Treatment
	- Design and Management Revegetation Program
Rock Mechanics	-
Soil Mechanics	-
Chemist	- Water Chemistry Specialist
Service Engineer	- Provision of Power, Steam, Heat, and Water
Civil Engineer	- Layout of Surface Facilities, Roads, Rail, Etc.
Human Resources Management	- Providing a Work Environment that Attracts a Good Workforce and Encourages Quality Performance
Townsite Managers	- Domestic Water Supply
	- Sewage and Garbage Disposal
Legal Department	- Interpretation of Regulations
Public Relations Dept.	- Enhancing the Corporate Image

The Systems Approach must taken into account water use requirements, water quality effects on the performance and the nature of effluents, as well as the availability and cost of alternatives at each unit operation, considering at least the following:

Ore Type
Gangue Characteristics
Quality, Cost, and Availability of All Available Water Supplies and Requirements
Mining Operating

Underground Dewatering
Mill
Metallurgical Process Alternatives
Nature of Wasterock
Wasterock Disposal or Use
Tailings Disposal and Management
Water Treatment Plant
Soil Characteristics
Subsurface Geotechnics
Climate
Vegetation
Topography
Location
Relative Reagent Costs
Regulations
Other Uses for Water Downstream and Sensitivities
Nearby Cities and Townsites
Sewage Plants at Mine and Nearby Urban Areas
Garbage Disposal
Location of Power Plant Flyash Availability

During the last several decades, society has become technology-oriented and increasingly specialized. To apply the systems approach, what is needed is a multi-disciplined coordinator with a strong technical background, operating experience, proven ability to weigh cost benefits, and management clout.

The main aim of a mining company is to make as good a profit as possible as well as long-term survival and growth. The water management focus should never lost site of this and should, therefore, be heavy on operating experience.

To make the systems approach work, it needs the dedication of all departments--each one must be aware of its role and potential roles. Usually, more information and education is needed than is currently available. To keep all the diverse interests working in the same direction, the water management staff must have the support of top management. The General Manager needs to be knowledgeable about water management and for this, he needs good staff support.

WATER MANAGEMENT AND METALLURGICAL ENGINEERING

BAKER and BHAPPU (Undated) concluded an excellent review on the effects of mineral processing on water with the following statement:

"NEED FOR ENVIRONMENTAL AWARENESS AND TRAINING

It is obvious that the mineral process engineer of today and the future has to play a dual role, that of a metallurgist as well as environmentalist. Traditionally, he is trained in the basic sciences and engineering common to both fields. What is needed is a keen awareness and concern to fulfill the dual responsibility that our mineral-based society has imposed on him.

This awareness and technical competence can only be developed through a realistic and well-balanced engineering curriculum. It is not necessary that the undergraduate engineer be required to take a specific course or courses in environmental science and engineering. However, it is essential that the student be made aware of the similarities in the two fields throughout all the engineering courses. With proper orientation and a minimum of deviation an instructor can do an adequate job of training the mineral process engineer so that he will be in a position to solve the environmental problems facing him in his professional career."

BAKER and BHAPPU (?) examined the problem mainly from the standpoint of mineral flotation processes in southwestern Arizona from porphyry deposits and their statement implies that environment related aspects be integrated into university training.

This report concludes that metallurgical and mineral processing engineers require specific formal education and practical training in water chemistry and water treatment technologies with a bias toward the needs of mineral processing facilities and also, education on the environmental aspects of metal and reagent impact and behavior. Without this type of background, it will be that much longer before a really appropriate systems approach to water management can evolve. Cross-breeding of disciplines usually yields valuable results. The biggest environmental problem of mining and milling is acid mine drainage, and this will not be resolved without understanding the fundamentals of the problem and adopting a systems approach.

The Real Cost of Water

Cost of New Water
Cost of Delivery System
Cost of Distribution System
Cost of Treatment to Discharge Effluent
Cost of Storage, Monitoring
Cost of Sludge, Concentrate Disposal
Cost of Filing Reports
(Incremental Resource Recovered)

HONEYMOON URANIUM PROJECT

24,000 PPM TDS, 10,800 PPM Cl^-

The Cost of Recycling Water

Corrosion Damage to Pipes and Equipment
Corrosion Control Measures
Scale Control
Effects of Scale (Reduced Throughput, Higher HP)
Energy Consumption Increase Due to Scale on Heat Exchange
Metallurgical Efficiency Cost
Water Reclamation Cost of Pumps, Pipes
Pumping Costs
Cost of In-Plant Water Treatment
Extra Reagent Consumption Due to Recycled Water Quality
(Reagent Recovery Cost)
(Energy Recovery Cost in Recycling Warm Solutions)
(Metallurgical Performance Improvements Using Recycle Water)

EXAMPLES

HONEYMOON PROJECT, AUSTRALIA

The Honeymoon project was uranium resource in the Australia outback. It was clearly an attractive in situ leach target. The problem was that there was no fresh water available for many tens of miles.

The local aquifer contains brackish water with a very TDS level (30,000 ppm), including a high chloride level. If conventional uranium recovery by ion exchange resins were to be used, recoveries would be so poor as to be unworkable at the high Cl^- levels in solution.

An example of overlap between metallurgical process selection and development and water management in terms of the systems approach that this report promotes is the discovery that by adding more salt to the available water to reach very high chloride concentrations, a point on the equilibrium curve for ion exchange adsorption can be reached where uranyl chloride loads to a reasonable level. In this case, uranium would be eluted from the loaded resin by a more dilute solution. Instead of working in the range A-B of the curve for adsorption/elution, it would be possible to work in the range C-B for uranium recovery using the existing poor-quality water. This would surely be much less expensive than desalinating the water and applying the conventional process.

A CANADIAN URANIUM MILL: NO SYSTEMS APPROACH

A large uranium mine-mill complex on the edge of a lake practiced macro recycling of water. Treated tailings decant water is discharged to the lake system. Lake water is used in the mine and mill.

The mill put in a request to the utilities department of the structured large organization for an additional 3,000-4,000 gpm water for use in the mill. They were advised that this would not be possible for six months. Reason: It would take that long to expand the water treatment plant which was operating at capacity.

Utilities water was being treated by IX for use in the boilers to make steam for uranium leaching which requires a heated pulp. Somehow, the total water needs of the mill were being supplied from this plant, including that used in the grinding circuit. Only after more water was not available was an investigation started which asked the question as to whether lakewater could be directly used in the mill. This is an extreme case of not using a systems approach to water management.

SYSTEMS APPROACH - SELECTING A WATER TREATMENT PROCESS

Many factors must be taken into account when selecting a water treatment process. To illustrate the systems approach idea, consider the case where several reagents are considered for base metal removal from effluents. In the first case, hydroxides precipitation may not get solubilities down quite as far as needed. Sulfide precipitation may achieve the low solubility but has the disadvantage of being more difficult to remove the suspended precipitate and uncertainty about stability of sludge disposal and toxicity if excess reagent is used. A combination of sulfide and lime can possibly solve all the problems:

- It reduces the metal levels in solution to that of sulfide precipitation.
- Lime-sulfide precipitates settle faster than lime precipitates and yielding lower S/S than for sulfide precipitate settling.
- Only a small fraction of the quantity of sulfide reagent is required compared with straight sulfide precipitation.

This is an example of how a systems approach can help solve problems.

THE OVERALL WATER COST FOR TWO GOLD RECOVERY OPERATIONS

Generalized costs for mining and milling at a large Witwatersrand gold-uranium mine and at a Nevada heap leaching operation are compared below along with a total overall water and water quality related cost guestimate. This shows that, depending on circumstances, water quality control and modification can justify significant attention and investment in the ore case, very much less in the second case. Some heap leaching operations, however, will not be feasible at all without appropriate water quality modification.

	RSA Au-U $/t Ore	Nevada HL $/t Ore
Removal of Overburden	--	4t @ $4.00/t - $4.00
Ore Mining	$45.00/t	$1.00/t - 1.00
Total Mining Cost	$45.00/t	$5.00/t
Metallurgical Cost	3.50/t	2.00/t
	$58.50/t	$7.00/t

Water Cost

Pipes, Pumps, Valves, Say 8% of Overall Cost in RSA	$4.85	±$0.50/t
Water Consumption	1.0 m^3/t	0.2 m^3/t
	0.17/m^3 water	0.17/m^3 Water
	$0.17/t Ore	$ 0.03/t Ore
"Total" Water Cost	$5.02/t Ore	$ 0.53/t Ore

SCOPE OF WATER MANAGEMENT

The scope of water management in a mining operation should enable a "systems approach" to be adoped which includes the mine, mine services, mill, tailings, wasterock, catchment area, smelter, refinery, water impoundment, water source(s), and water treatment as well as environmental monitoring program. By applying a systems approach, the water cost savings by recycling more water and possible resulting effluent treatment cost savings can be weighed against the "cost" of metallurgical inefficiencies resulting from higher incremental salt buildup and possible increased corrosion or scale control costs.

The scope of water management should, therefore, encompass all facets of the operation. For example, if it costs more to dispose of a precipitate formed in the water treatment plant in a landfill than the penalties incurred by shipping it to a smelter blended into a concentrate, then this could conceivably also be the business of the water manager.

Scope of water management can include:

- Water Balance Design and Control
- Salt Balance Design and Control
- Input at Plant Design Stage
- Matching Metallurgical Processes with Available Water Qualities
- Meeting Regulations and Permit Reporting Requirements
- Problem Solving when Permit Conditions Threaten to be or are Exceeded
- Negotiating New Permits or Renewals
- Negotiating Less Costly or Simplification of Permit Compliance
- Corrosion Protection or Avoidance
- Scale Inhibition Measures
- Water Conservation Measures
- Negotiation of Improved Water Prices
- Preservation of Water Quality
- Seeking Synergisms to Save Pumping/Water Costs
- Resource Recovery from Water
- Cost Reduction Through Innovation
- Public Relations
- Development of Management Support

Water and salt balance computation in mine-mill complexes is in itself an emerging science which has been greatly furthered by the now general availability of cost-effective desk top computers and software.

In applying for permits for new operations, it is now nearly always necessary to project the water balance for the operation in advance. This means that in addition to predicting the water balance, the salt balance must also be known so that the impact of recycled solutions on the metallurgical processes can be predicted, and the extent of salt bleed determined as well as the size and type of water treatment facility.

Expertise in this area is relatively limited, but the following companies are known to be developing computer models for water and salt balance modelling:

Don't get just an equipment supplier. Think of RCC's systems engineering approach.

There are dozens of suppliers offering equipment for an individual element of water and wastewater treatment. RCC gives you a single-source solution for water and wastewater control. You'll be assured of getting the most advanced technology and the best equipment to fit your need, from simple end-of-pipe treatment to an integrated plant water system. And after startup, we'll still be there providing continued service for data monitoring, operator training, or critical parts handling.

RCC is experienced in applying systems analysis to the design and retrofit of water systems in all phases of industry. Our clients include chemical processing plants, mining companies, pulp and paper mills, oil refineries, synthetic fuel producers, distilleries, electric utilities, and government agencies.

RCC's engineering services

Laboratory and pilot plant testing
Systems analysis and conceptual design
Detailed design and procurement
Installation and construction management
Project management and control
Startup and checkout
Operator training
Continued customer support

Water Management Systems

RCC assumes single-source responsibility for industrial water systems

Our technology delivers cost-effective solutions

The water that powers industry, irrigates the land, and quenches our thirst is a finite resource.

If the historic trend continues, clean water will become a diminishing resource in this decade. Industrial growth is placing extraordinary demands on water supplies. Regulations for disposal of wastewater are becoming ever more complex.

Critical point analysis has been overlooked when it comes to water management.

In nearly every industrial facility, a "systems approach is used to develop the primary process or manufacture the product. Many economic, technical, and regulatory factors are carefully analyzed and integrated into a system solution. This same logical approach is seldom applied to the supply, use, reuse, and disposal of water. Yet, water systems analysis and good water management can save industry millions of dollars and can significantly reduce regulatory burdens.

The quality and composition of wastewater streams affect economics.

To minimize the influence of these factors, RCC's systems engineering approach considers the total water system from supply through disposal. The objective is to design a water system to maximize water recycle and reuse, reduce waste streams to meet discharge requirements, and recover valuable resources from the streams. Consistently, our integrated system design offers a life cycle cost less than end-of-pipe treatment alternatives.

An integrated systems approach is more than a discrete product or process.

It is a logical step-by-step understanding of all aspects of a water problem and its relation to plant operation. The economic and risk alternatives to maximize reuse and minimize discharge are given careful systematic attention to produce effective long-term solutions.

Just treating and discharging water is spending a lot of money to throw something away.

We offer more cost-effective solutions. An RCC water management system reduces intake requirements, cascading the effluent of one process to another process or operation. Treatment of each effluent can be tailored to its contaminants and its next use. This integrated systems approach affords the most economical solution to the problem.

We realize your waste and recycle requirements are special.

Every operation has a set of unique water considerations. RCC is a water management company that can identify and understand your requirements. We can act as your engineer to analyze your objectives and assess your alternatives. We can design the optimum system to solve your specific water recovery problem. We will even procure the equipment, install and test the system, and train your operators. Our customers call RCC the best turnkey service in the business.

3.8-million-gal/day wastewater treatment facility

Total zero liquid discharge by 1985 was a goal set for this 1,700-MW coal-fired power station. After thorough engineering study and careful analysis of environmental regulations, an optimum wastewater treatment system was integrated into plant operations. The technology employed included neutralization and clarification, demineralization, sludge dewatering, reverse osmosis, and brine concentration. The human elements of plant operation were also addressed and a water conservation training program was developed to strengthen work functions.

Water use cut 55%—zero liquid discharge protected

A Washington industrial plant's water inflow consistently exceeded its evaporating capacity. The company asked RCC to evaluate its process waters to develop treatment alternatives and to select the most cost-effective method to correct the problem and remain at zero discharge.

Our solution uses a crucible wash water reuse process to minimize contamination of storm lake water and a Brine Concentrator process to evaporate 80 gal/min of the plant's surplus water. Much of the plant's internal water was cascaded or placed on closed or recirculating loops. Zero liquid discharge was maintained and the company's water consumption has been reduced from about 300,000 gal/day to less than 70,000 gal/day.

Wastewater inventory reduced by 50%

A significant and unexpected growth of wastewater was about to cause major problems at a southeastern utility's 900-MW coal-fired station. RCC moved onsite, analyzed all major streams and produced a near-term solution to intercept and divert rainwater and reroute some existing wastewater. Simultaneously, we developed long-term alternatives to better manage the internal streams. Now operating, our water management system has not only reduced actual wastewater outflows, but also allowed zero liquid discharge.

CHAPTER 3

REVIEW OF WATER USE, AVAILABILITY AND COST AT MINES AND MILLS

The purpose of this part of the investigation was to determine answers to some of the following questions:

- How much net new water is required by different types of mineral processing and metallurgical operations.
- What quantity of water is recycled in the operation.
- What are the limitations on water recycling in the plant.
- What factors influence the specific fresh water consumption requirements.
- If there are more than one metallurgical process that can be used to recover a mineral or metal, is one more water efficient than the other. Does one avoid environmentally sensitive reagents needed by the other or reagents that cause problems in recycled solutions.
- What is the range in cost of water at metallurgical operations, and what factors influence the cost, i.e., are there ways for an existing operation to save water costs.
- What is the structure of water costs? If costs are all in a fixed overhead cost to be distributed over the amount of water used, with a negligible amount for water itself, then little will be saved by conserving water.
- Is the process adaptable to use alternate water sources, e.g., seawater, high TDS groundwater, or treated sewage water.

These questions and more were asked at each of the operations visited. Although many operations do compile water balances defining how water is used in their mine-mill complexes, very often these are not very definitive. Only some milling operations meter flows to different sections of their plant.

It was remarkable how many mine-mill complexes were visited and, despite the willingness of the staff involved, the visit was concluded without adequate data to obtain a clear picture of how water is used in the operation. Historically, mill operators were not concerned about the amount of water that they consumed, nor how much is discharged, or what became of the rest as long as there was enough water available. This was

particularly true in locations where there is no limit to the amount of water available and no restriction on the volume of effluent. The answer to pollution was, more often than not, dilution. Since effluents were also usually discharged without treatment, there was little or nothing to be saved in recycling more water. If treatment is needed before effluent can be discharged, then the mill operator may not be concerned because that is taken care of by the environmental control department, and they have their own budget.

Other operators will proudly advise that they now use, for example, 75% recycle water in their mill. Defining water use in this way is meaningless though. For example, if one operator uses 1 m^3 of water per ton of ore treated of which none is recycled, and another uses 4 tons of water per ton ore of which 75% is recycled, they both have a net use of 1 m^3 water per ton ore. One recycles 0% while the other recycles 75%, yet in terms of net water consumption and net discharge of water per ton ore treated, both situations are identical.

At any particular operation, the mill superintendent looking after the mill more often than not was not involved in its design and erection; he inherited that. He is bent on optimizing the primary functions of the mill--namely the recovery and grade of concentrate or product. To achieve this, he knows that he needs a certain pulp density, i.e., volume of water per ton solids treated. Once he has optimized these parameters, if he has extra time and energy, he may next work on using more recycle water if pressure is put on him by the services department, the environmental department, or by management to do so. If the driving force requiring recycling is a shortage in water supply, then he is likely to think in terms of the net volume of fresh water per ton used per ton of ore treated. If his motivation is to reduce the amount of effluent, then he will think in those terms. He may step by step introduce recycled water to each part of his circuit, one at a time, carefully exsmining the results each time to see whether grade or recovery has been affected. As he does so, he is likely to think in terms of percentage of his total water use that is fresh water as he competes with himself to make progress. If he wants to appear to be responding to outside pressures but is concerned about the effect of using more recycle water in his plant from the grade/recovery standpoint, he could also use more recycle water but also add more fresh water to offset its effects, and he may actually be recycling a bigger percentage of water but still be using more fresh water per ton ore treated.

It was clear at virtually every operation visited that attempts were being made to reduce the net fresh water intake. In Canada, the motivation was in reducing the volume of effluent to be treated. In South Africa and South West Africa/Namibia, the motivation lay in conserving water supply at a time of drought. In some parts of the world, there is no fresh water, and the operations have had to be based on the poor quality water available at site or even seawater.

The volume of water used in a variety of operations per ton ore is summarized in the table below. So is the cost of water used overall and per ton ore. It is noteworthy how many mill operators do not know the cost of their water unless they are located in a part of the world where water is particularly scarce or expensive.

Another factor that makes it difficult sometimes to compare operations in terms of net water consumption is the amount of water that must be removed by pumping from underground mines. This minewater may be used in the mill, thereby replacing fresh water needs. If an operation is located in a very arid climate, it does not necessarily mean that it will be short of water. RØSSING URANIUM LTD. in one of the world's driest climates has reduced their water consumption dramatically through a wide range of conservation measures because water in the Namib Desert location is scarce. At Grants, New Mexico, the Quivira Uranium Mine could be expected to be short of water, but so much groundwater needs to be pumped from the mines that most of it has to be discarded to a "creek." Near Yuma, Arizona, the Chemgold heap leaching operation is located in a country as dry as the Namib Desert, yet they have as much water as they can possibly need from the Colorado River through a deeded right.

In mine-mill operations, water of different qualities can be suitable for one part of the process but not another. For example, in complex sulfide flotation plants, recycle water is usable just about everywhere in the process except, it is found, in the Pb-Cu separation circuit. It is not known what causes the separation efficiency to suffer when recycle water is used at that point.

Several conclusions were possible based on the still rather limited spectrum of data available on water use:

- The amount of water that is needed for metallurgical operations is directly proportional to the amount available.

- The cost of water per se, although it can be a substantial amount of money, is generally a negligible factor in the overall operating cost structure of a mine-mill complex.

- The "total" cost of water used in a mine-mill complex can be much more than the cost of the water per se, when the cost of effluent treatment, scale inhibition, corrosion, and impact of water quality on metallurgical recovery are factored in.

- Some processes are very much more water efficient than others for recovery of the same metals, i.e., heap leaching vs. conventional agitation leaching.

- One of the problems in using the data gathered during this investigation for comparisons of the amount of water consumed for a given type of process is that it

has not been possible to avoid "comparing apples with oranges." For example, at one mine-mill complex, the housing for employees will be included in the water consumption data but not at another. Elsewhere, although water for housing amounts to as much as for mineral processing and is not figured into the mill fresh water needs, treated sewage is blended with recycle water, is a large factor in overall water supply, but is not shown in the net fresh water consumption figure. In some cases, water consumed in the refinery is also lumped into the water consumption data. For example, at INCO's Ontario Division, the mine-mill-smelter-refinery complex water use was given as follows:

Fresh Water Use:	
Mills, Smelter, and Refinery	53,418 m^3/d
Townsites	59,072 m^3/d
Mines	18,479 m^3/d
Reclaimed Water:	
Mill Water Recycling	98,795 m^3/d
Smelters	26,473 m^3/d
Mines	48,000 m^3/d

It is interesting to note that the domestic fresh water needs of the townsite exceed that needed for the mills, smelter, and refinery. The same applies at Vaal Reefs in South Africa. Water is used in so many different integrated operations at Copper Cliff that is was not possible to reduce it to a usable basis for comparison with, for example. the mills and smelter-refinery at Timmins.

- In some cases, the catchment area of the tailings disposal may be very large, and large quantities of water may be accumulated which augment tailings recycle water.

- Elsewhere, there may be a net evaporation loss from the tailings area, but large quantities of available minewater.

- Another factor that complicates the comparison of water recycling between one operation and another is that some mill circuits recycle more solution internally whereas others depend more on external recycle.

For example, many gold mining operations keep cyanide out of their milling circuits by milling in fresh water which is mostly recovered by a thickener installed to thicken the cyclone overflow in the classification circuit following the grind. The thickener overflow is recirculated to the front of the milling circuit whereas the thickener underflow is repulped with barren solution which contains cyanide and lime. This mill circuit has two internal water recycle loops. Yet another is the

tailings repulping step which is likely to use tailings decant solution. Internal recycle of solutions is not observed in summary tables.

- When water is expensive as for example at the Black Mountain Mine/Mill at Aggeneys, South Africa, (R1.20/m^3), there is often not much advantage to using less water as the price charged is based mainly on an overhead levy to recover the capital investment in the pipeline and the pumps and not so much for the water actually consumed. If water consumption is cut back, then the unit price simply goes up.

- In computing water needs for an operation, it can be misleading to simply look at the water requirements for a mill. Consider the following water consumption at the Black Mountain Mineral Development operation in the Northern Cape Province of South Africa where rainfall averages 4" per year, and evaporation is 65" per year:

Metallurgical Plant	4,000 m^3/d
Township	4,000 m^3/d
Road Maintenance	500 m^3/d
For Mine Backfill	1,200 m^3/d
To Shaft	800 m^3/d
Cooling, Compressors, Etc.	500 m^3/d
Annual Average	11,000 m^3/d
Summer	14,500 m^3/d

Water for metallurgical purposes in this case account for only 29-36% of the total water needs of the operations.

- Water Use in mining and milling is clearly site specific, and generalization are not appropriate.

USE OF WATER IN MINES AND MILLS

Mines

1. Potable Water Operations
2. Boiler Feedwater
3. Backfill Transport of Tailings
   Backfill Moisture Content in Place
4. Dust Control in Mine Workings and Roadways
5. Cooling Underground, Compressors
6. Dust Control at Working Faces
7. Hydraulic Power for Underground Tools
8. Underground Hydropower Generation

Mills

1. Potable Water
2. Boiler Feedwater
3. To Grinding Circuit
4. To Flotation Circuit
5. Filtration or CCD Plant Washwater
6. Tailings Repulp Water

Smelter/Refinery

1. Potable Water
2. Process Water
3. Cooling Water
4. Scrubber Water
5. Acid Plant

Townsite

1. Potable Water

ANNUAL COST OF WATER FOR MINE-MILL OPERATIONS

How much does water cost for mine-mill operations? This varies considerably from site to site obviously, and the results of a survey are summarized in the following table. Water ranges in price from "free," i.e., the cost of pumping it, to A\$1.00/m^3 or U.S.\$0.65 in Western Australia around the Kalgoorlie area where it has to be pumped about 600 Km from the nearest source. In the survey, one small operation in the California desert reported a water cost of \$3.97/m^3 reflecting the cost of hauling water.

Overall cost of water for an operation ranges from "free" to \$1.62 million/year. Although in this case the largest water bill went to the largest mine, the size of an operation has little to do with its water bill.

ANNUAL COST OF 'NEW' WATER INTAKE AT MINE-MILL OPERATIONS

Operation	Location	Facility	Volume Used m^3/Year	Unit Cost $/$m^3$	Total Cost (Annual)
Black Mountain	South Africa	Mill	1.46mm	$0.30	$ 450,000
	(Desert)	Township	1.46mm	$0.30	$ 450,000

INTRODUCTION

All water-related problems in mines and mills stem from three main problems: Too much water; not enough of it; and/or its quality. The greatest need of all is how, at the end of the life of the mine and mill, to restore the site to be able to abandon it without a perpetual maintanance program and water treatment plant.

Mine Dewatering

Both operating mines and abandoned mines may become the subject of dewatering needs. During operations, it may be necessary to keep water out of a mine. BOSMAN (?) has pointed out that if an abandoned mine can be kept dry, then the generation of acid mine drainage may be reduced. Minewater may also be the most available water resource for a mine-mill project. Minewater may or may not be acid or contain species that interfere with metallurgical recovery if it is used as process water, but it nearly always contains species that require removal before it can be discharged without environmental damage.

Scranton Anthracite Coalfields

Water has resulted in the closure of mines in the past. The Scranton anthracite coalfield was a major producer of anthracite coal. Numerous operations worked independently and, collectively, their many pumps kept the water table below a manageable level. Until one of the operators penetrated the bed of a river and within that day, all the operations were flooded.

The Argo Tunnel

In 1943, when a lateral from the Kansas drift struck water in one of the workings served by the 21,000 foot long Argo Tunnel, four miners were drowned, and all the operations served by the tunnel were closed never to open again.

Friedensville Zinc Mine, Pennsylvania

The Friedensville Zinc Mine, Pennsylvania, is a famous wet mine that had been kept dry for many decades by giant pumps--enough to form a picturesque creek in the Saucon Valley. The closure of this mine in 1984 has resulted in the flooding of its workings, and it is highly unlikely that it will ever open again. Water pumped from this mine was so low in nutrients that they had to be added to promote aquatic life in the discharge.

West Driefontein Gold Mine

In the 1970's, one of the world's richest gold mines, West Driefontein, hit a massive underground river which flooded part of its deep underground workings, threatening the whole operation. This was solved by segregating the flooded area and plugging the shaft, allowing the rest of the mine to operate.

ERPM

All present-day operating mines on the central Witwatersrand are connected underground and, in order to keep them from flooding, water is drained from three of the deeper ones into which minewater from surrounding operations drains. The East Rand Proprietary Mines Ltd. (ERPM) is one of these. 64,000 m^3/d of acid mine drainage is first partially neutralized underground and then pumped to the surface where it is treated by HDS neutralization and discharged to the Vaal Dam drainage.

ERGO, at Brakpan on the eastern Witwatersrand, treats 1.6 million tons per month of tailings. It uses water pumped from Durban Deep and from Grootvlei, adjacent underground gold mines. This minewater, although the acidity can be neutralized with lime, contains quantities of dissolved salts which are now a cause of concern because of their contribution to TDS buildup in the Vaal Dam--the regional water supply source

serving 1.6 million inhabitants. Pressure is being exerted on the mining industry to consider desalination of this water to reduce the Vaal Dam TDS load, and an innovative new reverse osmosis process has been tested successfully at this and at the ERPM site. See the trip report in Appendix I on ERPM.

The Dolomites - West Rand

West of Johannesburg on the Witwatersrand, a large area of land is underlain by a dolomitic formation that hosts a very large regional aquifer containing good quality water. Mining operations connect the surface with deep underground gold and uranium ore deposits located in formations deep below the dolomites with the result that water drains from the dolomites into the mineworkings below. The dolomites in the immediate vicinity of the mines are dewatered, and the water is recharged to the aquifer some distance away. Associated with the change in hydrology that this has brought about, numerous large sinkholes have resulted in the dewatered areas. This has resulted in the virtual evacuation of some of the affected areas and several unfortunate sinkhole incidents. It is believed that this is a problem related to mine dewatering.

Getchell Mine, Nevada

In Nevada, the abandoned open pit at the Getchell Mine near Winnemucca contained 300-400 million gallons of water which needed to be dewatered before work could resume on evaluating resources below the pit. Deep-well injection of this water was estimated to cost $2.5-3.5 million. The quality of this water made it unsuitable for direct discharge to drainage in Humbold County. The answer to this problem appears to have been to get into the agriculture business and to use the water to irrigate crops. More details on this solution might be available from:

FRM MINERALS, INC.
66 South Van Gordon Street
Lakewood, CO 80228
Eric Peterson

Gilman Mine, Colorado

The Gilman Mine in Colorado, which recently shut down after a very long life, is another example which is described in Appendix I. In this case, clean underground minewater has been segregated for direct discharge while acid mine drainage was treated by lime neutralization and settling underground before discharge to the Eagle River.

In the case of Gilman, if the mine is abandoned allowing the water level to reach a critical level, the acid minewater would overflow into the clean water reservoir, and it would all have to be treated before discharge. Also, the pump serving the clean water discharge function, being made of cast iron, would soon be corroded. The water treatment facility

BETHLEHEM MINES CORP.: PANTHER VALLEY ANTHRACITE MINE

does not have the capacity to treat the combined flow, and the owner-operator of the mine was low enough on cash for lime deliveries to have been suspended and the power company to have served notice of its intention to cut power. At the same time, the state of Colorado had named the tailings pond to which the precipitate sludge from the underground sludge is disposed of as a Superfund site.

MR. JACK MERCHANT
(303) 328-6349

Kromdraai Coal Mine

At the worked out Kromdraai Coal Mine in the Transvaal, minewater is pumped to the surface and treated by lime neutralization and HDS settling. The treated water, virtually free of metal cations except calcium, magnesium, and alkali metals, was pumped to a local military base as potable water. It soon had the army on the run. Mine water is often loaded with sulfate which has a cathartic effect.

Schullsburg Zine District

For many years, the Eagle Picher Company mined zinc and lead in Wisconsin. When the ore was depleted and the mines abandoned, the pumps were shut off, and the mines were allowed to flood. Some time later, a regional groundwater quality problem resulted in which extremely high $SO_4^=$ and Mg levels were detected in nearby wellwaters rendering them unsuitable for their traditional uses. Mine dewatering may have an impact on water quality that becomes evident only after the mining operation ceases.

PROFESSOR JAMES I. HOFFMAN
College of Letters and Science
University of Wisconsin
Oshkosh, WI 54901

Panther Valley Division, Bethlehem Mines Corp.

At their Panther Valley Division near Tamaqua, Pennsylvania, the Bethlehem Steel Company mines anthracite coal from a huge steeply dipping seam. The area was originally mined by conventional underground prining, and the workings were dewatered by large pumps installed to depths of 600 feet. The present pit is nearly 600 feet deep and extends well below the original underground workings.

Prior to neutralization of the acidic minewater, it is thoroughly aerated to drive off CO_2 as an effective means of reducing its lime consuming capacity. Minewater environments at stabilized or warm temperatures especially often host bacteria that get their energy from reactions with sulfide minerals and carbon source. These bacteria liberate CO_2 which is kept in solution as HCO_3^-. At depth, the CO_2 solubility is also increased. Consequently, when lime is added to such water, it can exhibit extremely scaling

characteristics generating excessive sludge volumes. By pre-aeration at a near neutral pH, CO_2 is displaced from solution, and both lime consumption and sludge volumes are reduced accordingly. Additional information may be objtained from:

When using minewater for metallurgical process solutions, caution should be exerted as in some cases its water chemistry may cause interferences.

Falconbridge Onaping Mine

At Falconbridge's Onaping Mine in Ontario, minewater pumped from underground is scaling and every so often, the vertical pipes carrying it must be reamed out with a special tool. Eventually, the pipes were wearing thin, and the operation was faced with a likely need of replacing the pipeline. By connecting this mine with the new adjacent Craig Mine, the new dewatering system in the adjacent shaft was able to do the job for both, thereby avoiding the need to replace the older worn out system in the Onaping shaft.

Abandoned Mines

Mining, unlike forestry or agriculture, has to do with a depletable resource. Once the ore has been mined, the site is abandoned. Typical mine life may be two to twenty years, although a few have even celebrated over 100 years of operation.

One major problem facing the industry is the contamination of surface and groundwater caused by abandoned mines. These old workings may fill up with water which then seeps through fissures in the rock to eventually reach an aquifer. Alternatively, the mine may incorporate an inclined shaft which allows mine drainage to flow from a portal.

A major concern to regulators is how existing mines will be closed to prevent this from occurring.

By no means all mines generate acid water. Some are not wet at all. Others involve materials that do not contain sulfides, or the gangue is so basic that any acid generated from sulfide particles is immediately neutralized. Mine drainage can, infact, be at a relatively high alkaline pH, say 8, but this is rare. In one case, mine drainage at a high pH when it flowed into a pond to which nutrients are added in the form of treated sewage effluent from a nearby settlement, resulted in an algal bloom. In some cases, minewater must be acidified to bring down the pH in order to meet ammonia criteria for discharge.

Rooiberg Tin Mine, Transvaal

At one of the Rooiberg tin mines in the Transvaal, minewater has an almost neutral pH, but it contains 5-6 ppm F^- which is in excess of the 1.5 mg/l F limit for potable water. Since this is one of the only sources of water in the area, it has to be treated for fluoride removal before it can be rendered potable.

Copper-Molybdenum Flotation, U.S.A.

The San Manuel copper-molybdenum mine-mill complex is believed to have developed its own flotation technique for copper-molybdenum separation. Eventually, they abandoned this method and changed over to the conventional NaHS depression technique because oils, greases, and hydraulic fluids that contaminated their ore and minewater interferred with the process. Oils and hydraulic fluids in minewater at operating mines can present metallurgical problems when this water is used in the metallurgical operations.

INCO Ltd., Cu-Ni Flotation

At INCO mines and mills at some point in the past, it was found that hydraulic fluid losses underground were excessive, and that these losses resulted in metallurgical impact until the cause of high frequency hydraulic line rupturing was found and rectified.

It is beyond the scope of this report to review the techniques and equipment employed in mine dewatering or constraints on the materials used in dewatering pumps. From a water management and treatment point of view, there are some basic points to bear in mind:

1) The likelihood of corrosive or scaling waters which may require pipes and pumps of special materials.

2) Suspended solids are abrasive to pumps and pipes and are often best removed underground. Special separating thickener-clarifiers are used for this purpose and described in Chapter 12.

3) Prior to pumping acid mine water from underground, its quality may require adjustment, if necessary, to avoid scale or corrosion problems in the pipes.

4) Water pumped from underground is likely to have been in contact with oxidizing mineralized rocks and may contain undesirable contaminants. It may require treatment before it can be discharged to the environment.

5) Bacterial processes can contribute several chemical species to water including native sulfur sulfides, HCO_3, and organic species. Rotting timbers can contribute sulfo lignates, etc.

6) Acid mine drainage abatement or treatment is dealt with a length in other sections of this report.

Tailings and Wasterock Runoff and Seepage

Acid mine drainage has been identified as the greatest water-related problem facing the mining and mineral processing industry. This term includes water that is discharged from mines as well as that which drains from waste materials generated by the mining industry. A large part of this report is dedicated to acid mine drainage prevention and cure. The magnitude of the acid mine drainage problem is greater than expected. Despite the tens of millions of dollars spent on research, an economical way to prevent acid mine drainage from occurring does not seem to have been found yet.

Acid mine drainage is generated by wasterock and tailings from base metal mines, collieries, uranium operations, gold and silver mines, and even at times from rock moved in roadmaking--wherever sulfide-containing ores are mined and milled.

Open pit mine descriptions refer to strip ratios of 2:1, 5:1, 10:1, etc., and sometimes higher. That means that for each ton of ore mined, 2, 5, or 10, etc. tons of waste must be removed. If this waste contains sulfide minerals it is a likely source of acid mine drainage, and there is much more of this waste than ore. Mine waste disposal represents a problem with respect to acid mine drainage inhibition or control that has often been overlooked in the past. For example, mine waste has typically been used to build rail and roadbeds or as fill in building workshop areas and storage yards or tailings dam walls.

Many times this mine waste is ideal for the purpose, but the problem arises when it contains sulfides, possibly sulfides containing base metals. Crushed wasterock piles are a perfect trickle filter, and sulfides will oxidize rapidly yielding acid mine drainage solutions. At the Onaping mine-mill complex in Ontario, a half mile roadway built of crushed wasterock alongside a creek carrying their final tailings effluent results in the

increase of nickel levels from 0.9 to 1.0 ppm which is the permit limit for their discharge. This is only one of numerous examples that could be cited.

Tailings impoundments for modern mines can be very large and represent large catchment areas which collect precipitation. Also, the surface is exposed to the sun and air and during dry spells, it accumulates high concentrations of salts transported from the interior of the tailings by capillary action. Precipitation draining from these areas can carry high levels of dissolved solids. Water draining into the Vaal Dam after extended dry periods followed by a downpour contains a noticably higher dissolved solids content than normal when has been ascribed by KEMPE (1983) to this phenomenon.

One might have expected that as the surface leaches, the concentration of salts in the runoff would diminish with time. The capillary transport phenomenon which continuously replenishes and concentrates salts on the surface of tailings is a more powerful factor than is commonly appreciated. There are effective counter measures that can be applied, but first the problem must be recognized.

ROUSE (1984, personal communication) has observed a location where the pH of tailings remain close to neutral throughout tailings except at the surface. This is interpreted as due to vertical transportation of ferrous sulfate to the surface by capilliary action where it is oxidized to ferric sulfate + acid with a drop in pH only at the surface.

The problem acid mine drainage generation in surface runoff from tailings in South Africa with its net evaporation, generally dry climate does have remedies which are discussed later in this report as long as the problem is recognized and dealt with. In net precipitation areas, this problem is less easy to solve.

Huge wasterock piles have accumulated around the large Witwatersrand gold-uranium mines. These unquestionably are AMD generators, but the extent has still not been quantified. Elsewhere in the world, careful wasterock management, including selecting a site with soil of very low permeability, comingling acid generating waste with highly alkaline calcerous wastes or depositing acid generating waste on top of acid consuming waste, and providing provision for drainage collection can make wasterock AMD generation into a manageable problem. The extent of AMD generation by wasterock piles does not yet seem to be fully appreciated by the mining industry or regulators, although it is certainly being addressed in the revised RCRA (Resources Conservation and Recovery Act) regulations now being formulated by the U.S. Congress.

Acid mine drainage generation from tailings and wasterock can continue for centuries after these materials are lain down. The prospect of "perpetual" management, runoff collection from these sites, and treatment of the collected water certainly compounds the problem.

Quality of Available Water Supply

Mineral deposits are not made to order but are discovered wherever they may be. For a variety of reasons, they are more likely to be discovered in remote arid regions. Mills are, for economic reasons, best located adjacent or close to the ore deposits. Consequently, there is not as much leeway in the site selection of mines and mills as there might be for an oil refinery, chemical plant, or other types of industry.

Generally, it is after the mining plan has been devised, the mill and mineral process selected and pilot tested, and the decision made to go ahead that the project managers set off to find a water source. Of course, if it is known in advance that water is likely to be a limiting factor, then water supply factors are addressed early.

Apart from availability of water which is a prime concern, the quality of the available water can be a major problem.

A classic case is the western Australia gold fields around Kalgoorlie where locally available water is highly saline. Fresh water is pumped in over a distance of 600 kilometers from near Perth at a price of A$1.00/m^3.

Purchased Water

Most regional water supplies are good quality, and no problems were identified in their use when available.

River Water

The quality of river water varies greatly from river to river and from season to season.

Vaal Reefs Exploration and Mining Company uses water from the Vaal River to supplement the regional supply. This water is attractively priced. River water may carry a high suspended solids load which should be settled for application in some sections of the metallurgical process. However, it is unlikely that river water containing sediment would be a problem if used in the grinding circuit, for example. Where river water has a high suspended solids load, one way to avoid this problem is to draw from wells in alluvia and sand alongside the river which provides a means of drawing filtered water. In some parts of the world, vegetation growing along rivers can break loose, and the vegetable matter floating in the river water can present a problem at certain times of the year.

Elsewhere, river flow can fluctuate significantly between dry and wet seasons. Flash flooding can threaten water quality and pump stations. Generally, river water quality is satisfactory for metallurgical use and usually, after settling, filtration, and disinfection, also for potable use.

Rand Mines Milling and Mining Co. Ltd., in treating tailings on the outskirts of the city of Johannesburg, uses creekwater from a nearby stream. Metallurgical problems have been partially ascribed to the poor quality of this water which is impacted upstream by other industries including an abattoir. The species that cause the problem have not been identified, but the presence of an abattoir upstream implies that oxygen depletion (BOD) and fulvic acids could be investigated as a problem.

Humic acis and sulfo lignates can be generated by vegetation, timbers, and wood left to rot in water. These species can cause metallurgical problems if present.

High levels of calcium and magnesium in river water are possible, and this can result in the need for larger doses of reagents when used in flotation circuits.

Groundwater

Water quality varies dramatically from aquifer to aquifer. Some aquifers contain extremely pure water; others are so high in dissolved salts or toxic contaminants that the water is unusable for most applications.

In California, several heap leaching operations have shut down in the Mojave Desert because the only water available has such a high TDS level that it interferes with just about every phase of the recovery process, i.e., the heap permeability is reduced, sprinkler heads and pipelines scale up, activated carbon or filterpresses scale up, etc.

One operator in the Mojave successfully uses groundwater saturated with magnesium chloride for heap leaching followed by carbon adsorption of gold.

In Australia, particularly western Australia, groundwater can contain up to 100,000 mg/l TDS which, surprisingly, is used satisfactorily in some CIP operations. The salts consist largely of NaCl, and there is even an indication that gold leaching may be enhanced by the presence of chlorides at this level, but it has not been confirmed. Certainly the ore leaches extremely rapidly.

Wellwater used in conjunction with certain types of ore and reagents in some Nevada heap leaching operations has resulted in severe scaling problems. Under pressure (i.e., at depth in a well), water can dissolve very much more CO_2 than at ambient conditions. When the pH is adjusted with lime or calcium is added to solution through contact with the ore, this is likely to precipitate $CaCO_3$ as scale. This phenomenon, which is related to the wellknown carbonate-bicarbonate equilibrium which is often overlooked in the field, is a common factor in heap leaching.

Many aquifers yield very hard water, and many metallurgical operations require steam. This means that boiler feed water must be demineralized which is expensive. Scale impairs heat exchanger surfaces and must be dealt with.

High TDS groundwater may also be very corrosive, which can present an operating expense problem.

Treated Sewage Water

In some parts of the world where water is in short supply, sewage plant treated effluent has been considered as a supplementary source of water. It is believed that Chuquiquamata Division of CODELCO is one operation which is forced to use recycled sewage water in their copper recovery operation. No information is available on the impact of using this water on metallurgical recovery.

At the Climax Molybdenum Mine, a relatively small volume of sewage was discharged to the tailings pond from which water was decanted for reuse in the mill. Based on laboratory tests, sewage addition to tailings would have a deleterious effect on flotation recoveries if it were not for the addition of activated charcoal with the tailings. As long as sewage was added to the tailings impoundment at Climax, activated carbon was added. Both practices stopped at Climax when the mining camp moved to Leadville some years ago, and the present staff do not have details available.

Extensive testwork at Anglo American Research Laboratories showed that when sewage plant effluents are mixed with tailings pond decant water for use in flotation plants recovering pyrite and gold from Witwatersrand-type tailings, sometimes does and sometimes does not have an effect on recovery. Could this have something to do with sporadic bacterial or algal blooms or detergents?

Operators at the President Brand Gold Mining Company, Welkom OFS are convinced that the addition of sewage reclaim water to their flotation circuits results in deterioration in recovery sometimes, but not always. They believe that if the affected water is first used in the Peabody scrubbers to cool roaster gases and remove particulates, then it can safely be used in the flotation process. President Brand floats tailings at an acid pH.

At Vaal Reefs Exploration and Mining Co. Ltd., one of the largest gold mining complexes in the world, mine hostel sewage water after biofiltration is mixed with tailings and decanted. Use of this water in the gold and uranium leach circuits has not been found to have an impact on recovery.

Anglo Transvaal Research Laboratories in the outskirts of Johannesburg has conducted laboratory flotation tests to recover pyrite and gold using high pH flotation such as they employ at their Hartebeestfontein Gold Mining Co. and Lorraine operations. They tested

treated sewage water from two sewage plants at Stilfontein, and their preliminary results showed that the old sewage plant effluent, which employs a biofilter, did result in a serious negative impact on flotation recovery. However, effluent from the new plant, which uses an activated sludge process, does not. Quality of effluent from small town sewage treatment plants varies from day to day, and it is not at all clear yet under what conditions the sewage plant effluent will or will not interfere with flotation results. The tests, however, are highly significant in that they indicate that depending on how it is treated, sewage effluent interference in flotation of sulfide minerals and gold may be avoidable.

Witwatersrand mines and mills are labor intensive operations employing many thousands of workers. Sewage plant effluents amount to very large volume of water, typically 2,000 m^3/d from just one hostel. This water represents an attractive supplementary water resource.

In the deep Witwatersrand mines, underground cooling also consumes large quantities of water. It would be economically attractive to use sewage plant treated effluent as cooling water underground. This, in practice, presents two major problems. First, ammonia in the sewage water attacked the copper-nickel refrigeration coils. This problem can be solved by the addition of certain inhibitors to the water or by changing the coil material. Second, all water used underground in South African mines must be disinfected and rendered potable as mineworkers are accustomed to drinking it where they find it.

This is usually achieved by subjecting water to breakpoint chlorination prior to use in the mines. However, because of the ammonia content in reclaimed sewage water, chlorine consumption at 10 Cl_2:1NH_3 would be excessive. The possibility of partial chlorination as a disinfecting method and the health effects of chloramine are now being evaluated.

It is not known what species in recycled sewage water cause metallurgical problems in flotation plants. One theory is that detergents may be the cause; another is that polyelectrolytes used in the sewage treatment process are responsible.

Gencor Ltd. metallurgists refuse to consider the use of recycled sewage water anywhere near uranium operations that use solvent extraction for uranium recovery because they believe organic species in the water would interfere with SX recoveries.

In the desert southwest of the U.S.A., most copper-molybdenum operations also avoid the use of reclaimed sewage water in their metallurgical operations in nearly all cases in the belief that it interfers with recoveries in the flotation circuit.

Most operator prejudice toward the use of reclaimed sewage water is based on empirical observations. Very little information is available on what species cause the problems and what can be done to correct the problem. New sewage treatment processes are described

which certainly can reduce ammonia and phosphate to levels below which they are a problem.

Tailings Return Water

Water used in metallurgical processes or to repulp tailings can be partially recovered from tailings ponds by decantation and returned to the operaton as process water. As water is recycled in this way, dissolved salts concentrations will build up until, ultimately, they result in metallurgical interference or other problems such as scale or corrosion.

Specific metallurgical problems are discussed separately--for example, depressed loading of uranium on IX resins due to competition for loading sites with other species in the recycled water, and the use of recycled water in flotation circuits which were the two main problem areas identified.

Some operators are very successful at cleaning up their tailings water, rendering it suitable for recycle in various ways.

Typical species that build up in recycled tailings water and which interfere with metallurgical processes are:

$CaSO_4$, $CaCO_3$:	Scale.
Bacteria:	Corrosion.
Cl^-:	Corosion, especially in acid pressure reactors at elevated temperature.
$SO_4^=$, Cl^-:	Competition with uranium for IX adsorption sites.
SiO_2:	Silica fouling of filter media; fouling of IX resins; possible enhanced crud formation in SX plants.
Base Metals, Arsenic:	Interference with Merrill-Crowe precipitation of gold and silver unless purged in "barren bleed." Increased cyanide consumption. Chromate and copper in recycle solution to complex sulfide flotation ruins selectivity.
Thiosalts:	Above a certain level in effluent, these oxidise with resultant pH drop in the receiving waters; may generate S^0 in suspension which fouls IX resins and carbon pores.

Magnesium:	Believed to modify the adsorption characteristics of gold onto carbon in CIP. Forms insoluble Ca-oleate with some flotation reagents resulting in higher reagent consumption needs.
Bismuth:	Believed to affect gold loading onto carbon in CIP.
Ferrous Ions:	Interferes with gold desorption from carbon when present in solution at the time gold is adsorbed.
Oil and Grease:	Problems in gold adsorption on carbon and flotation.
Cyanide:	Problems with preg robbing in grind in some gold mill water recycle and reduced pyrite-gold recovery in some flotation circuits.

WATER PROBLEMS IN MINES

Cooling and Ventilation

Very large quantities of water are used in cooling deep Witwatersrand gold and uranium mines. The prospect of using treated sewage reclaim water for this purpose as a supplemental water source was discussed above. The main problems seem to be the ammonia content which corrodes cooling coils made of copper-nickel and the heavy demand for Cl_2 if it is used to disinfect the water prior to its use as a coolant.

This has resulted in several innovative R&D projects in South Africa.

According to the Calgon Corp., the corrosion of Cu-Ni cooling coils can be corrected by treating the coils with one of their products:

CALGON CORP.
Post Office Box 1346
Pittsburgh, PA 15230
(412) 777-8000
Dr. Bennett Boffardi
Russ Kirwin

Disinfection of the treated sewage water usually requires treatment with chlorine to breakpoint. However, each 1 ppm NH_3 in the water consumes at least 10 mg/l CL_2 to achieve this. Several alternatives are possible to solve this problem which is mainly one of expense and the continuous addition of chlorides to the reacted water:

1) Remove the ammonia first through a more effective biological tertiary sewage treatment process, e.g., activated sludge, Badenpho process.

2) Remove ammonia by adsorption on clinoptilolite clay as descrived in Chapter 27 on ammonia removal.

3) Determine whether partial chlorination yielding chloramines would be an effective bactericide and whether the chloramines are themselves safe contaminants.

4) Use chlorine dioxide for sterilization of the water in lieu of chlorine. ClO_2 can be generated on site using equipment provided by:

CALGON CORP.
Post Office Box 1346
Pittsburgh, PA 15230
(412) 777-8000
Dr. Bennett Boffardi
Russ Kirwin

FLOCCATAN (PTY) LTD.
Box 52662
Saxonwold 2132
South Africa
(011) 442-9001
Andrew Wilkinson

5) The use of silver-impregnated activated carbon is used to sterilize water in hospitals. It is not known whether the same approach could be developed for sterilization of sewage plant effluent water to render it suitable in underground cooling systems.

6) Treated sewage water might be used in a closed loop refrigeration system that does not allow it to be released underground, thereby avoiding the need for disinfection.

7) Alternative underground cooling systems such as the use of liquified or chilled compressed air might be investigated.

8) Hydraulically powered tools have been developed that are powered by the hydrostatic head from the underground workings to the surface using water as opposed to oil as the hydraulic fluid. There is the opportunity to use this also as a supplementary cooling system, and special water management and treatment measures will be needed to implement this.

Ventilation

Ventilation deals with air distribution, but it is rumored that the use of water injection into the inlet airstream is being considered as a secondary cooling method. If treated

sewage water is to be considered for this application, then it will have first to be disinfected and second, be free from detergents or foaming agents. It is not known how far along the evaluation of this concept has come or even whether it is real or not.

Underground Sludges

In underground workings, invariably large quantities of finely divided materials are caught up with water, and it has been found to be more economical to settle out these solids as sludges and to pump the water to the surface separately to reduce abrasion.

Several innovations in sludge separation and handling were encountered in passing which may be of interest.

Various designs of clarifier have been used underground. The main needs of these are that they should be reliable and operator-proof, and compact enough to be installed in confined underground workings where headroom is restricted or expensive to excavate.

The development of an improved cylindro-conical underground settler by the CSIR was sponsored by Anglo American Corporation and Gencor Ltd., the two largest South African mining houses. Subsequently, the Anglo American Corporation introduced additional modifications. The recommended standard design of the improved cylindro-conical settler was described in an internal Anglo American Research Laboratories report by MARSDEN (1980).

In the late 1950's and early 1960's, considerable attention was paid by the South African mining houses to the best and most economical procedures for settling and recovering sludge from underground mine water. Since large volumes of water needed treatment underground, the cost of flocculant was high, and it was concluded that a substantial cost savings could be realized by optimizing the balance between cost of settling the suspended solids and the cost of pumping, i.e., abrasion wear which is enhanced by the presence of solids. Studies by the National Mechanical Engineering Research Institute concluded that pumps handling water with relatively coarse particles were subject to high wear costs. Their report emphasized the advantages of vertical settlers rather than horizontal settlers for particle removal. The costs of excavations, chemical dosing, and labor all favored vertical settlers over horizontal settlers. An overflow turbidity of 340 mg/l was forecast in the "horizontal" settler compared with 25 mg/l for the vertical unit. Not only would pump wear be reduced, but gold losses in the turbidity carried in the overflow would be reduced by 90% using the vertical settler.

Because suspended particles in underground water are 90% smaller than 5 microns, at 5 microns particles settle at 1.6 mm/min. Settling of particles larger than 5 microns can be achieved in a settler at a rate of 2.2 m^3/m^2/day of surface area. Consequently,

flocculation was clearly essential to increase the settling rate and therefore the volume throughput.

Optimum flocculation is achieved by applying a violent mixing phase for floc formation followed by gentler agitation for floc conditioning to enlarge the floccules and increase their settling rate. There is a further need to withdraw sludge as rapidly as possible before it increases in density as well as to remove the overflow as uniformly as possible. The advocated technique was the vee notched launder developed at the Harmony Gold Mine.

In the cylindro-conical settler design, dirty inflow water enters the settler tangentially near the cylindrical side and outside an inner skirt. The concept of inclining the skirt at 15° and feeding into a small anular space which, as the water spirals downward englarges, is the concept developed by the NEMRI and CSRI. Water enters the settler rapidly and turbulently and gradually slows down with a concurrent reduction of turbulence. This enhances its hydroclynimic performance considerably. Another superior feature is the fact that the cross section of the skirt is exactly 50% of the total (outer) cylindrical cross section, hence there is no change in velocity, and consequently, a minimal increase in turbulence as the downward flow rounds the bottom of the skirt and starts moving upwards inside the skirt. Many tests undertaken on a 1.5 m Ø model at the West Driefontein Gold Mine clearly demonstrated the hydrodynamic advantages gained from maintaining an even flow.

THE AARL-CSIR SETTLER

MARSDEN (1980) recommended further improvements in the standard CSIR cylindro-conical settler design:

1) The mode of entry of the minewater to the settler was changed to minimize air entrainment.

2) Air vent passages diameter was increased to 150 mm to allow entrained air to escape without lifting water.

3) The distance upstream and condition under which flocculants are added is changed. Where a polyacrylamide flocculant, e.g., Separan MG200, is used, the more violent and instantaneous the mixing, the better. The applicable criterion is the total energy input during mixing. A certain energy quotient is required for mixing, and the more rapidly this is applied, the better. Thereafter, for the second agglomeration phase, only relatively gentle but still turbulent flow is required. A 100 meter channel at a slope of 1 in 200 allows adequate agglomeration of the floccules.

5) pH adjustment is recommended. If the discharge water is not limed, the pH value often drops to pH 2.5-3.0. Acid corrosion of pipes and pumps is high. Weld heat affected zone corrosion where pipes are welded along their seams is also likely to occur.

   If water is over limed to a pH of 9.0-10.0, calcium carbonate and/or calcium sulfate sealing of the pipe column occurs, and periodic cleaning using a spiked scouring ball or even by removing the pipes may be necessary.

   If the water pH is adjusted to 7.6-8.0, experience has shown that corrosion, including weld-heat affected corrosion, is minimized while scaling is very slow. The suggested pH is best ascertained by weekly determination of the water analysis and adjusting its Langelier index by lime additions to +0.5.

6) For general design purposes, MARSDEN (1980) recommends using an upflow velocity of 60 mm/minute (1 mm per second) for design purposes. This value can be used to calculate the daily capacity even though during peak periods actual flow velocity can be almost double. The capacities of common diameters of cylindrical settlers is given as follows:

Diameter Area			Settler Flow Rate		
m	Ft	m^2	l/s	m^3/h	Ml/d
6.1	20	29.2	29.2	105	2.52
7.9	26	49.4	49.4	178	4.27
9.1	30	65.7	65.7	237	5.68

Lamella Clarifers

If space underground is a constraint, it is very surprising that lamella clarifiers have not caught on in South African mines for underground sludge separation, provided scale in the plate pack can be controlled, and indications are that it can through optimization of the Langelier index.

Lamella-type clarifiers are offered by:

SERPAC PLATE CLAIRFIERS:

Another wellknown Lamella thickener-clarifier is offered by:

PARKSON CORP.
Box 408399
Fort Lauderdale, FL 33340
(305) 974-6610

Disinfection

Water used on mines as potable water requires disinfection prior to use. The disinfection process employed should destroy coliform bacteria and also viruses.

On mines in North America in which a sparate potable water system is installed, it is adequate to disinfect only the potable water supply. In large labor-intensive mines in developing nations and some developed countries such as South Africa where

labor-intensive mining methods are practiced, all water supplied to underground mines must be disinfected. The reason is that mineworkers tend to drink water wherever they find it.

Chlorination

The conventional method of water disinfection is through breakpoint chlorination as practiced at most municipal water treatment plants. These units are standard equipment supplied by such companies as:

PENNWALT CORP.
Three Parkway
Philadelphia, PA 19102
(215) 587-7183

PENNWALT CORP.
Wallace and Tiernan Div.
925 Warden Avenue
Scarborough, Ontario
Canada M1L 4C5

Small volumes of water can be chlorinated using sodium hypochlorite, but this would be too expensive for large systems.

The chemistry of disinfection is described by CULP, WESNER and CULP (1977). They point out that suspended solids in the water to be treated should be reduced to the lowest possible level prior to chlorination to assure maximum contact between remaining pathogens and the disinfectant.

At Kloof Gold Mining Co. on the Witwatersrand, the cost of chlorination of treated sewage effluent has been reduced by using a sewage treatment process that reduces ammonia levels to less than 0.5 mg/l.

Chlorine Dioxide

Chlorine dioxide is claimed to be an effective disinfectant which is not consumed by ammonia. Chlorine dioxide systems and generators are offered by:

CALGON CORP.

Iodine can be used to prevent mine absenteeism

A revolutionary water purification system that could help reduce absenteeism will soon be launched in South Africa. The system, based on Iodine disinfection, has proved to be trouble-free, inexpensive and easy to install. Developed in America by Continental Water Conditioning Corp a fully-owned subsidiary of Millipore Intertech Inc.

Miners at stope level are at times in danger of drinking contaminated water, usually resulting in periods of disabilitating sickness. While chlorination systems are the answer in urban areas where vast volume is used, the problem of the smaller consumer locations remains a problem.

Iodine is more stable chemically than chlorine and other germicides and less affected by sunlight, PH and temperature, giving more lasting protection against micro-organisms. Iodine is less volatile, safer to work with and less noticeable to the taste than chlorine.

By using iodinators a wide spectrum of micro-organisms (see table) is destroyed.

Iodine in a saturated solution of a fixed temperature is always of consistent strength. Through a simple valving system a small portion of the saturated iodine solution is introduced into the main water stream where it is greatly diluted to a range of 0,5 part to 1,0 part per million.

An iodinamics test kit informs the user if the concentration of iodine is right. If not, then feed supply can be quickly adjusted. There are no moving parts, no need for electricity, and, unlike chlorinators, there is no need for venting, wiring or complicated maintenance.

Installation is simple. The iodinator is connected directly into the water system between the pump and storage tank. The low concentration of iodine residual must be retained in a holding tank for a few moments before use so the germicidal affect can take place. The smallest iodinator can treat approximately 730 000 *l* of water (at 0,5 ppm residual feed) before it needs refilling. When the iodinator is empty a cap is unscrewed and crystals are poured in; the whole operation taking moments.

Drawing of Iodinator shows how water moving through the system becomes saturated with iodine and is then mixed in precise quantities with the main water stream to control germs.

A problem that might face mines is dissolved or precipitated iron in the water. Dissolved iron has no effect on the function of effectiveness of the iodinator nor will iodine precipitate the dissolved iron.

If the level of precipitated iron is high enough to be visible, prefiltration is recommended to prevent plugage. If iron bacteria presents a problem then there are no remedies to apply.

Septic tanks too are safe. Bacterial demand is so great that the trace amount of iodine is quickly rendered ineffective as a germicide, leaving no harmful effects.

Hydrogen sulphide problems too can be treated. It takes about 7,4 ppm of iodine residual to offset each part per million of hydrogen sulphide.

There have been extensive tests in America to determine the long term effect on health. No claims have been made that drinking iodinated water has caused any ill effects.

Costing about R250 for the unit and some R100 a year for maintenance the system would appear to be something that the mines will look closely at with regard to their health problems.

To show how effectively iodinators can control organisms a partial list follows — the iodinator controls many other kinds of organisms as well: ■

Approximate contact time in which these potentially dangerous organisms can be controlled with an Iidinamics® Iodinator® (0,5 ppm iodine, pH 7,5, 20°-26°C)

Bacteria	Disease caused	Approximate Contact Time
Escherichia coli	Cystitis of urinary tract	50 seconds*
Salmonella typhosa P-4	Typhoid fever; gastro-enteritis	1 minute**
Salmonella typhosa P-5	Typhoid fever; gastro-enteritis	1 minute**
Salmonella typhosa P-10	Typhoid fever; gastro-enteritis	1 minute**
Salmonella paratyphi P-2	Paratyphoid fever	1 minute**
Salmonella schottmuelleri P-3	Paratyphoid fever	2 minutes**
Salmonella typhimurium P-6	Food poisoning	5 minutes**
Shigella flexneri P-7	Paradysentery	2 minutes**
Shigella dysentariae 11 P-8	Dysentery; intestinal ulcers	2 minutes**
Shigella sonnei P-9	Paradysentery	2 minutes**
Streptococcus fecalis E-40	Can be pathogenic	2 minutes**
Staphylococcus aureus	Septicemia; brain abscess; enteritis	50 seconds +
Staphylococcus epidermidis	Subacute endorcarditis	1 minute +
Virus		
Poliovirus Type 1	Polio	9 minutes*

WATER CHLORINATION Vol. 5

Chemistry, Environmental Impact and Health Effects

Robert L. Jolley, Environmental Chemist, Oak Ridge National Laboratory, Oak Ridge Tennessee; **Richard J. Bull**, U.S. EPA, Cincinnati; **William P. Davis**, U.S. EPA, Gulf Breeze, Florida; **Sidney Katz**, ORNL; **Morris H. Roberts, Jr.**, College of William and Mary; and **Vivian A. Jacobs**, ORNL, Editors

NEW 85

- Comprehensive, systematic, holistic
- The significant original contributions of the last 3 years
- International in scope, encyclopedic treatment
- Rigorously peer-reviewed, reliable
- Up-to-date chlorination research, developments
- Alternatives
- For your convenience, in a single volume
- 1,650 est. pages

This work will be cited thousands of times in articles, papers, chapters, and books.

OF PRIMARY INTEREST TO: Chemists, public health scientists, water treatment specialists, activated carbon adsorption, regulators, toxicologists, utilities, libraries.

This is a comprehensive examination of the chemistry, environmental impact, and health effects of water chlorination as practiced in the areas of water treatment, wastewater disinfection, and cooling water use. *It is the peer-reviewed proceedings of the Fifth Conference on Water Chlorination held at the College of William and Mary*, Williamsburg, Virginia, June 3-8, 1984.

The volume, however, represents more than the proceedings. Organized in a systematic and holistic fashion, it can be read either as a scientific treatise or selectively as individual research and development papers. The philosophy of organization and presentation makes this work truly unique. Rigorously peer-reviewed, up-to-date research papers represent significant original contributions to research in the areas of chemistry, toxicology, environmental toxicity, and public health. In addition to chlorination, this work also deals with the chemistry and effects of alternatives (e.g., ozone, chlorine dioxide, chloramines).

There is no recent book similar to this one. Includes all the ramifications of water chlorination practice, presents the most significant research and developments that have occurred within the last three years. Also details significant new developments in epidemiology, risk assessment, toxicology, and photochemistry of oxidants.

Unique to this work also are its comprehensive treatment of chemistry, toxicology, health effects, and environmental effects.

BENEFICIAL USERS OF THIS HOLISTIC REFERENCE: People of numerous disciplines and areas of interest will find much valuable information and data in this comprehensive, peer-reviewed book. *Chemists* will especially want the sections dealing with chemistry of water chlorination, chlorine demand reaction, chloramination reaction, photochemistry of oxidants, chemical methods, reaction kinetics, alternatives to chlorination (e.g. O_3, ClO_2). *Public health* people will value *Water Chlorination 5* for risk associated with water chlorination, toxicology, mutagenicity, carcinogenicity, disinfection, water treatment. *Water treatment* people, for process chemistry, chemical effects of drinking water treatment processes. *Activated carbon adsorption*, for disinfection of drinking waters and wastewaters, chloroorganic precursors. *Regulators*, for risk, chemical effects, toxicology, health and environmental effects. *Biologists*, for environmental effects, toxicology, bioassy results, species and community changes associated with chlorinated outfalls. *Toxicologists* will use the information on toxicity, mutagenicity, carcinogenicity, risk, and disinfection. *Utilities* will need sections that cover environmental effects, bioassy results, biofouling studies, modeling, chemistry of cooling waters, chlorine minimization.

July 1985 **1,650 est. pages** **hundreds of figures, tables** **thousands of references** **ISBN 0-87371-005-3** **$69.95**

ORGANIZED IN 16 MAIN SUBJECT AREAS: More complete even than previous editions, *Water Chlorination 5* organizes 116 original chapters into 16 principal categories, as follows:

1. Water Chlorination: Basic Issues
2. Risk: The Bottom Line
3. Epidemiological Considerations
4. Carcinogenic and Mutagenic Effects
5. Toxicology of Disinfectants and Their By-Products
6. Aquatic Models and Tumor Induction
7. Environmental Effects
8. Disinfection
9. Reaction Dynamics
10. Chlorine Demand Reactions
11. Chemistry of Chloramination
12. Photochemistry of Oxidants
13. Chemical Methods
14. Drinking Water Treatment
15. Cooling Water Treatment
16. Wastewater Treatment

LEWIS PUBLISHERS, INC.

P.O. Drawer 519
Chelsea, Michigan 48118

It is known that chlorine dioxide was being considered as one possible way to disinfect treated dewage water for reuse underground, but the evaluation seemed in 1984 to be at an early stage.

Ultraviolet Light

Ultraviolet light is used in several non-mining applications as a means of disinfecting water. It is not known whether this treatment is cost-effective or whether it also destroys viruses. U-V disinfection systems are available from:

Carbon-Silver

Silver impregnated carbon is used to disinfect water used in hospitals. It is not known how effective this method would be on a massive scale for cooling water nor whether viruses would also be destroyed.

SCALE FORMATION

When water from mines and mills is recycled, especially where sulfuric acid leach processes have been employed or where levels of HCO_3^- are present and the solutions/tailings neutralized, then scale is likely to form in pumps, pipes, tanks, etc.

Acid mine drainage on the Witwatersrand is typically at pH 2.5-3.0. Neutralization with lime generates substantial gypsum and other scale-forming species in the water.

Experience has shown that by optimizing the Langelier index at around pH 6.7-7.2, that scale formation in underground pipes can be minimized.

Scale formation is a really serious problem at operations that reclaim Witwatersrand mine-mill dumps. The partially oxidized sulfides in the dump material generates sulfuric acid which reacts with lime added with the dumps when they were laid down. At ERGO, for example, dump materials are reslurried with recycle water and treated by flotation followed by sulfuric acid leaching for uranium. This all adds sulfate to the system. Finally, the tailings pH is raised followed by gold cyanidation. Ultimately, solution is decanted and returned to the plant. Also, sulfate-rich minewater is also used in the operation. The high sulfate levels combined with lime for pH adjustment results in water

with high sulfate levels. Surprisingly, the tailings reclaim water return lines are not very prone to scale formation. However, monitor water used to repulp tailings presents a scale problem; so much so that, on occasion, operators have resorted to the use of explosives to try and fracture scale on the inside of the pipe.

Scale formation is a very serious problem in many different operations. Apart from the one cited above, the following additional examples of scale problems were noted:

1) Numerous heap leaching operations experience scale formation in their pipes and even on activated carbon or in the heap which require counter measures.

2) At Brunswick Mining and at Noranda's Geco Division, acid mine drainage was neutralized with lime and the precipitate settled in a Lamella plate thickener. Although Lamella thickeners are used successfully for AMD precipitate thickening at several other operations, in these cases the system failed due to excessive gypsum scaling.

3) At Noranda Grey Eagle mines in California, gold cyanidation tailings seepage and decant water are treated by alkaline chlorination for cyanide and metals removal. Scaling in the alkaline chlorination reactors and thickener was a problem as was excessive solids formation. It is suspected that some of this might be avoided by vigorous aeration of the solution at a slightly acid pH to drive off CO_2 before lime addition. Much of the precipitate is expected to be due to $CaCO_3$ precipitation as a result of HCO_3 in the water and lime used in gold leaching even though pH control for cyanide destruction uses NaOH.

4) At Delta Manganese where high sulfate solutions are pumped from one part of the plant to another, scale in the pipes results in the need for a seven-man, full-time scale control crew who, armed with sledgehammers, have disfigured several pipes in the plant.

5) In in-situ leaching with high $CO_3^{=}$ solution into which CO_2 is injected as a lixiviant and complexing agent for uranium, the pregnant solutions on reducing the pressure prior to ion exchange become saturated with $CaCO_3$ which is kept in solution as a carbonate complex when excess CO_2 is present under pressure. Consequently, $\underline{CaCO_3}$ scaling occurs and can blind the ion exchange units unless counter measures are taken.

6) In the treatment of acid mine drainage by membrane and evaporative desalination processes, the level of ions increases steadily in the concentrate as water is recovered from the feed solution. Eventually the concentrate becomes supersaturated, and membrane fouling occurs unless counter measures are taken.

This is a limiting factor in the use of conventional membrane processes in desalination unless innovative systems are used which avoid the scale problem.

Typically, sequestering agents are used to inhibit or modify the nature of the scale formed. A typical sequestering agent is sodium hexametaphosphate. Excess sodium hexametaphosphate added converts to orthophosphate which can contribute to phosphate scale formation itself, or which can result in an effluent with a high phosphate content which can exceed effluent discharge limits itself.

Several water treatment companies specialize in scale control, and this aspect is discussed in further detail in a later chapter. Centainly, scale and scale prevention are two expensive problems facing the mining industry.

Among the expert companies that offer a scale prevention or scale control service are:

Corrosion

Corrosion is a major problem in many mine-mill complexes. Sometimes the cost of corrosion to an operation is not well known to the operators.

MOKKEN (1977) has provided a most constructive insight into the cost to the South African mining industry of corrosion. Based on the 1978 figures of R700 million in cost of materials of construction and equipment consumed as an operating cost in 1978 and 78 million tons of ore milled as provided by MOKKEN (1984), it is clear that breakages, abrasion, and corrosion costs the South African mining industry R8.97/t ($4.00/st). Of

this amount, a goodly fraction, speculatively say R2.00-R3.00/t is surely due to corrosion. MOKKEN's 1977 paper is inserted in the chapter on corrosion. Updated information would be available from:

MR. A. H. MOKKEN
Consultant

Lakefield Beroni 1500
South Africa
(011) 542-038

As solutions are recycled to conserve water or minimize the need for effluent treatment or effluent discharge, dissolved solids build up with the result that corrosion effects can be enhanced due to the water chemistry. A prime example of this is the metallurgical plant of RØSSING URANIUM LIMITED which recycles as much water from their tailings pond as possible. The limiting factor is corrosion due to chloride level buildup at low pH.

An interesting corrosion phenomenon has also been found to occur in which bacteria in the recycle solution deposit metal-rich precipitates on the inside surface of steel pipelines carrying this water back to the plant. Galvanic action between the precipitate and the steel of the pipe results in an electron flow which is highly corrosive, and pitting corrosion results. The high TDS of recycled solution acts as an electrolyte.

At Bethlehem Mines Division, Panther Valley Division, Tamaqua, Pennsylvania, acid minewater is pumped from a 600 foot deep anthracite coal pit. Similar bacterically deposited metal precipitate scale was observed on the interior of these pumps and pipes.

At a Witwatersrand gold and uranium mine, corrosion of Cu-Ni cooling coils in a refrigeration plant serving the underground workings was due to the test use of sewage treatment plan effluent containing 10-20 ppm NH_3 which corroded the alloy.

At Rustenburg Refiners, a platinum and base metals refinery near Rustenburg, Transvaal, the regional water supply containing elevated chloride levels was delivered for metallurgical use during the drought years 1982-1983-1984. Chloride levels increased further in process waters due to solution recycling. Eventually, the stainless steel 316L autoclaves used for high temperature and pressure hydrometallurgy were found to be corroding due to the reaction with chloride at the elevated T&P, to the extent that more than one had to be replaced.

At RØSSING URANIUM LTD., when the original plant was started up, the solution distributors in the CIX plant failed because a contractor installed mild steel instead of stainless 316L bolts which were soon corroded in the acid solution.

At the uranium leach circuit in the Western Areas Gold Mining Co. plant, a rubber-lined steel agitator propeller was was installed which , due to an imperfection in the coating, soon was corroded until all that was left of the propeller was two floppy rubber bags.

MOKKEN (1977) and MARSDEN (1980) both refer to the phenomenon of "trainline" corrosion of arc welded pipe seams which manifests itself in the form of longitudinal grooves at the juncture of the weld and parent metal. This type of corrosion has plagued the mining industry for the last 35 years and is attributable to the physical metallurgy of the pipe metal adjacent to the weld. Pipes carrying acid mine drainage are particularly subject to this type of corrosion unless its corrosiveness in counteracted or the pipes treated to avoid the problem.

At the Battle Mountain operation of DUVAL CORP. where water was pumped through a polyethylene pipe, severe corrosion caused failure of a steel section of pipe that was connected to the plastic waterline. The corrosion occurred very close to the juncture of the two pipes. Information on this phenomenon could be requested from:

RICHARD A. SUMIN
General Manager
Battle Mountain Operation
Duval Corporation
Post Office Box 451
Battle Mountain, NV 89820
(702) 635-2465

All of the above are examples of corrosion related to water quality and materials selection in the mine-mill environment. There are solutions to most corrosion problems, some of which are discussed in a separate chapter on corrosion.

At the RANDOL Workshop on Water Management, an illuminating discussion of what causes corrosion and how it can be prevented or minimized was presented by Bennet P. Boffardi of CALGON CORP. whose address is shown above.

Abrasion of Pipelines

The main cause of pipeline abrasion is due to the pumping of water containing mineral particles. Removal of such particles by settling was mentioned above under - "underground sludge." By removing the suspended solids from water, abrasion costs can be dramatically reduced.

include gold price

MINING FEATURE

THE VIABILITY OF THE GOLD MINING INDUSTRY IN RELATION TO THE RATIONAL USE OF MATERIALS OF CONSTRUCTION AND PROTECTION

By A.H. Mokken*

**Consulting Metallurgist, Union Corporation, Limited.*

Introduction

Gold production in South Africa, which has already reached its tenth decade, has depended for its continuity and viability on the contribution of two major resources. These are its human resources, composed of non-whites and whites in the approximate ratio of 9 to 1, with varying degrees of skills, and by its materials resources that have provided the tools, structures and equipment for the mining, transportation and processing of vast tonnages of ore and end products.

Collectively these two facilities, aided by such essential commodities as explosives, electric power, water and processing chemicals have produced in excess of one billion ounces of fine gold, equivalent to 31 104 metric tons, and account for about 80 percent of total operating and capital costs. It is clear, therefore, that the continued viability of the industry under a stable or steadily rising gold price will, essentially, remain a function of the proper control and use of these two major cost elements.

Great strides have been made by the industry in its endeavours to improve the working conditions, quality and effective utilisation of its human resources and research is continuing. However, the same cannot be said of its material resources and it is in this field, therefore, that major opportunities still await exploitation.

For many years the gold mining industry has provided opportunities for experimentation and research, opportunities that, in the field of materials selection and application have not been adequately visualized nor exploited. The main reason for this can be attributed to preoccupation with production and the absence of a facility solely concerned with materials, virtually the parallel of the many and varied facilities that cover the employment and welfare of its human resources.

The absence of such a facility in one of the country's major industries is believed to have had an adverse effect, technically and economically, on the industry as a whole and, in addition, on the productive status of manufacturing industry engaged on mining supplies.

Research, development and control in the field of materials of construction as components of plant and equipment in the mining industry should therefore not only change the direction of the cost trend of this resource, but would also bring with it an imposition of higher standards of production in manufacturing industry.

In a properly motivated environment research and development should thrive under conditions that provide ample and immediate scope for trials and tests and feed back and offer opportunity for technological innovation, a further resource that would not only contribute to the technical and economic health of the mining industry but could add to the country's exports in the form of spares and equipment, expertise and royalties.

Major Trends in the Gold Mining Industry

Figure 1 shows trends of four major elements in the productive and economic sector of the gold mining industry. Ominous signs of a narrowing of the profit gap are apparent. A redeeming feature is the increasing tonnage that is being hoisted and milled (although part of this ore came from surface dumps) and a levelling off in the fall of gold produced. This denotes continuity of operation and employment in a period when other sectors of the economy are on short time and, generally, in a depressed state.

The industry has no control over the selling price of its product and the future trend of the price remains uncertain. However, continuing inflation and political and monetary uncertainties should keep attention focussed on gold and for these reasons the chances of a steady improvement in price is viewed with a measure of controlled optimism. A further favourable factor, but perhaps only to a limited degree, is the magnitude of present world industrial demand which can now absorb South Africa's entire production. United States policy in relation to its vast stock of gold will, however, remain an unpredictable influence.

Costs of the Two Major Resources

Cost trends of the two major resources namely, labour and materials of construction and equipment are depicted graphically in Figure 2. Complete figures for 1976 are not to hand and the graphs therefore cover the eleven year period from 1965 to 1975. It is interesting to note that the amounts spent on these two resources are of much the same order.

Approach to the Problem of Cost Control

In his address to mine managers at the last annual general meeting of the Association of Mine Managers of South Africa, Mr. P.A. von Wielligh, Vice President of the Chamber of Mines, uttered the following pertinent warning:

"We must do everything in our power to ensure that, in the present economic circumstances, we do not add an unnecessary cent to mine working costs."

By stressing that managers should direct their attention at the smallest monetary unit implies that they should look at detail, at the finest, smallest detail of anything that could have a bearing on overall cost. This is good counsel. By interpreting the words "must" and "everything" as an unequivocal directive to industry, let us look at alternative approaches that could be followed towards optimising or rationalising the use of materials and equipment.

A problem would arive in finding an acceptable definition of "unnecessary cent". Putting the question to a number of mine managers could result in as many different interpretations. An inherent danger is that a measure of "price consciousness" rather than "cost consciousness" could arise with possible adverse effects on true costs. For was it not John Ruskin who observed that, whatever the price of an article, there will always be someone who could make it cheaper and of lower quality? Managers' decisions should therefore be made on as broad and as realistic a base as possible and this would apply in particular to marginal mines with large low grade ore reserves.

In the field of materials of construction one could divide the base into two main levels of expertise, the one centred on intelligent observation, rationalisation and standardisation and the other aimed at maintaining a continuous and in-depth scientific and technical investigation into the behaviour, quality and composition of all forms of materials used or proposed for use in the mining industry.

The Starting Point

In attempting to get the best and most out of our spares and equipment a good starting point would be to define, in each and every case and as adequately and as accurately as possible the underlying reasons for discard or failure.

It is admitted that, in some cases, the cause of failure or need for replacement might be fairly obvious. In others a level of technical knowledge and experience would be required whilst in the remainder only careful scientific investigation might or might not reveal the cause. In any case, potential improvements in design or quality that would emerge from such an assessment should be evaluated with the object of possible incorporation in future replacement orders.

By applying this approach even to the most menial of service parts as for example a hose mender and ensuring that the replacement would be an improvement on the original article, even if only to a small degree, repetition of inferior practices would be halted. If, for example, corrosion was the reason for failure of a mild steel hose mender, should the replacement be made in one or other quality of stainless steel and in what gauge or, bearing in mind the pernicious danger of crevice corrosion, would a plastic part be better? In any case the price of the article would be higher but would the cost, on a per ton mined basis and calculated over the life of the article, not be less? A properly controlled test would be needed to give the final answer.

Major Cost Items

Figures 3, 4, 5, 6 and 7 show, in order of decreasing magnitude the five categories that account for the highest expenditure on equipment and spares in the gold mining industry. Total disbursements on these five items amounted to R127 467 479 in 1976 or about 9 percent of total industry working costs.

Fig. 3

Fig. 4

Fig. 5

Fig. 6

Fig. 7

It should be noted that, as the graphs were prepared for a paper presented in 1984, and date back to 1957, they are still based on short tons.

In view of the marked influence on overall costs in the form of purchases of new material, expenditure on replacement and maintenance labour and loss of production resulting from equipment failure, it is possible that in this region the highest savings could be made by a proper approach. The expertise gained in controlling these costs would naturally rub-off on other items of lesser financial importance but they would nevertheless contribute to the overall objective.

Two complementary approaches present themselves. The first would be concerned with the application of known technology. The second would involve a more fundamental study of design and material usage as, for example, proper assessment of suitability for the specific requirements to which particular materials are subjected, possible improvements in quality and design, acceptability of substitute materials or even the generation of new materials tailored to meet particular needs.

Pipes, Valves and Fittings

The destructive forces that result in the need for replacement of this equipment could be grouped under corrosion, abrasion, erosion and mechanical damage including water hammer and cavitation.

In spite of the availability of known technology developed to protect pipe lines against the above hazards, it is surprising that more use has not been made of these facilities to overcome the problems of deterioration.

Fig. 8. *Compressed air pipe failure due to crevice corrosion.*

Figure 8 is a photograph of a 300 mm steel pipe that had to be removed from a mine shaft because of a blow-out at a badly corroded area near a flanged end. The pipe carried compressed air to the mine workings. Failure was clearly due to general external corrosion which was intensified at the point of failure by crevice corrosion underneath a pipe clamp. One can safely say that, if this pipe had been suitably protected, it would still have been in service and would have remained so for many years to come.

The cost of galvanizing the pipe would have added about 20 percent to its price, whilst a cold applied tape cover would have accounted for an additional 12 percent. If these considerations had been taken into account at the time of replacement of the corroded pipe, would they have been interpreted as unnecessary cents or as an investment with potential for capital appreciation and elimination of replacement costs?

Another cause of failure of pipe columns carrying mine waters, sometimes with catastrophic effect, is due to the phenomenon of "tramline" corrosion of submerged arc welded pipes, a type that manifests itself in the form of longitudinal grooves at the junction of weld and parent metal. This type of corrosion which has plagued the industry for the past 25 years, at least, is attributable to the physical metallurgy of the pipe metal adjacent to the weld. It was found to be more pronounced in single pass welds than in multi-pass welds which pointed to the beneficial effects of the heat treatment of subsequent passes on the previous run. Experiments have shown that a normalizing treatment

eliminates the problem but the practical difficulties of implementing this procedure on a large scale have hindered its adoption.

A similar phenomenon in the case of resistance welded pipes is manifesting itself in a new form to which the name "monorail" corrosion has been given. It occurs as a single groove in the centre of the fusion zone. Again here a normalizing treatment could be the answer.

A measure of success against corrosion of the outer walls of pipe columns has been achieved by galvanizing and by the application of a cold applied tape cover, whilst in the case of pipes handling abrasive slurries or corrosive liquids, rubber pipes or rubber lined steel pipes have proved very successful.

Attempts have been made to use plastic pipes of various qualities in both underground and surface installations. The measure of success has so far not been of a high order but it still remains an area that deserves closer attention before final unbiased conclusions are reached. Such attention can only be given by a separate facility, divorced from production pressures.

The use of stainless steel as pipe material, properly selected and used, also merits investigation as would the economics of solid drawn piping versus the fabricated form.

In the case of valves on which nearly 8 million Rand were spent in 1975, it is again surprising that in these days cast iron valves with broken wheels and bridges are still seen reaching mine scrap yards for re-conditioning. These practices undoubtedly account for the expenditure of many unnecessary cents in the form of inferior materials with a very uncertain life and augmented by the associated maintenance and replacement labour. It would not require a great deal of imagination to improve the position and, in fact, it could be a very interesting field for research and development aimed at producing an article that would not only meet the material requirements for the particular applications but that could withstand the ravages of indiscriminate operation.

Fig. 9. *Cast iron valve with broken wheel and bridge.*

Figure 9 shows a valve with broken wheel and bridge and Figure 10 shows an inscription that does not really meet the literary standards of many underground users.

Ropes and Fittings

In the interests of safety of men and equipment, close attention is given by the industry to the condition, quality and performance of winding ropes. Ropes are discarded for a number of reasons. These could include a fixed service life, inferior mechanical properties, rope distortion, corrosion, broken wires

Fig. 10. *Inscriptions that do not meet the literary standards of many underground workers.*

due to fatigue or mechanical damage, reduction in length due to the removal of statutory test pieces and accidental overload.

In spite of the high cost of ropes to the industry, but always bearing in mind the need for utmost caution, this would still appear to be an area where scientific research into the many aspects of rope manufacture, supported by comprehensive feed-back from industry, could lead to improvements that would not only benefit the local mining industry but carry its impact far beyond the country's borders.

It is estimated that scraper ropes account for about 60 to 70 percent of total rope costs. These ropes are exposed to extremes of abrasion, corrosion and stress under fatigue loading conditions and the question may well be asked whether protection of the ropes by a wear resistant coating would not merit investigation.

Scrapers, Haulages and Loaders
Grinding Mills and Grinding Media

These two categories are grouped together for the reason that a high percentage of replacement cost is due to the common factor of abrasive wear aided by corrosion.

A number of abrasive resistant alloys are used by the mines normally designated by name only as for example manganese steel, chrome steel, white iron, but never qualified by an exact specification nor controlled by adequate test. It is gratifying to note, however, that the position is changing and that the accent will be placed, increasingly, on material conforming to definite specifications. Only in this manner will it be possible to gather accurate information on the behaviour, performance and true cost of particular qualities of steel and iron alloys. These could then form the basis for comparison with the performance of new alloys under test.

The Republic is not a world leader in the production and supply of abrasion resistant alloys to meet the requirements of the worlds' mining industry. It could well be when viewed against the productive capacity of the country's steel casting industry which is about half that in the United Kingdom and in France, its vast resources of chromium and vanadium, and lesser resources of nickel and zirconium and, above all, a large facility for immediate and continuous testing of new alloys under highly abrasive conditions. The products of such research and development, coupled with sophisticated market research and assisted by generous tax concessions could generate a new resource that would create job opportunities, contribute to the gross domestic product and add to foreign exchange earnings. Quality of product and reliability of delivery would, however, be of paramount importance and would require the necessary supporting facilities.

Pumps

It is interesting to note that the amount spent annually on pumps and spares is a little below that for grinding mills and grinding media. It is true that large quantities of water of varying pH and solids in suspension are pumped daily, the ratio of water pumped to tons milled being of the order of 3 to 1. In addition all ore mined is eventually handled by pumps serving the ore processing stages in reduction plants. Much success has been achieved by the use of rubber in pumps handling ore slurries and favourable reports on the use of stainless steel for multi-stage pumps have been forthcoming. This observation seems to point to other reasons for the high pump costs, and exposes a field that merits closer attention.

It is confidently believed that substantial savings could be effected by research into pump design, materials of construction and standards of operation. Because of the universal need for pumps in a multitude of applications such research could become of great economic value.

Standardisation and Quality Control

The original emphasis on the need for standardisation in industry is attributed to a City of London iron merchant, H.J. Shelton, who wrote to the Times in 1895 complaining that rolled steel girders were being imported into Britain from Belgium and Germany because there was "too much individualism in this country where collective action would be economically advantageous". He stated further: "In this country no two professional men are agreed upon the size and weight of girders to employ for given work and the British Steel manufacturer is everlastingly changing his rolls or appliances at a greatly increased cost of manufacture to meet the irregular and unscientific requirements of professional architects and engineers".

It is interesting to note that, as a result of this complaint, an Engineering Standards Committee was set up in 1902. One of its actions was the reduction in the number of tramway rail sections from 75 to 5.

In South Africa, at about this time and following the discovery of gold, there was an urgent need for mining equipment which was imported from many different sources. The chaos that ensued called for a measure of standardisation and, as a result, the Transvaal Chamber of Mines appointed in 1905 its first Standardisation Committee to consider standardisation of machinery and other materials used by the industry. The committee seemed to have functioned for only a few years and was followed by an organisation known as the Committee for Standardization of Specifications for South African Materials.

It was only in 1946 when, owing to rapid post war industrialisation and a call for more organised testing facilities that the present South African Bureau of Standards came into being. A large piece of polished gold bearing rock, conspicuously placed in the portals of the present new building of the Bureau in Pretoria, symbolizes the fact that the needs of the mining industry have led to the development of standardisation in South Africa.

The Republic's gold mining industry consists at present of 41 producing mines, all still actively engaged on the extraction of gold (and in certain cases uranium) from the

milling and processing of about 76 million tons of ore annually.

In 1975 the industry earned R2 563 497 000, mostly in the form of foreign exchange and paid to the State in tax and lease payments R789 897 000. In addition, its dividend payments amounted to R522 867 200 and disbursements covering its cost of production, R1 243 854 000.

From these figures it is readily seen that the industry is a major pillar in the country's economic structure and therefore its continued existence and viability remain of vital importance. As explained before, the industry has no or very little control over the price of its product but it has a major hold on working costs, a hold which, when properly managed could still exercise a further profound influence on the standards of technology and quality of manufacture in the field of its overall activities.

The Republic's goldfields, as existing in the Transvaal and Orange Free State, are unique and of relatively uniform character. Mines working the deposit are, essentially, all doing the same thing. However, over the years, with advancing knowledge and facilities, systems and standards have changed and the newer mines have been able to incorporate the improved technology in their designs. In spite of this there are still large areas of common interest amongst the older and newer mines and these are therefore areas that could be exploited to common advantage. It should be observed here that, contrary to so many mining and industrial undertakings, the gold mines are not in competition with each other and therefore any technological advancement becomes available to the industry as a whole. In this way new standards are created which, in turn, become the bases for further development.

The mining industry in its present state could still benefit appreciably from the generation and adoption of standards on a group or industry basis. Such rationalisation should lead to lower manufacturing costs and to keener competition amongst suppliers.

It should be emphasized that standards should never be static. During the currency of their application they should be subjected to the closest scrutiny with a view to incorporating any new ideas and improvements when the designs are next reviewed. Economic factors must override resistance to change. To achieve such a condition in the mining industry would require a large measure of open mindedness and enthusiasm, motivated by enlightened leadership.

The development and maintenance of standards can only be successful if adequate facilities for control are established to exercise a continuing monitoring authority. Such a facility is available at the South African Bureau of Standards for articles carrying the Bureau mark. For the remainder the industry should establish its own facilities.

Design of Plant and Equipment

The word "design" as generally understood or used in the mining industry refers to the manifestation of an engineering concept in diagrammatic form. Important features of such a manifestation are shape, dimension, materials of construction and indicated standards of workmanship. The design could be a repetition of an existing facility or item of equipment with perhaps minor modifications or it could represent the embodiment in diagrammatic form of an entirely new concept either in its proto-type or final shape.

Undoubtedly the most important elements in the design are the materials of construction that have been selected to form the basis or framework and the functional parts of the equipment together with the manner of their use. Depending on the technical standards of selection and design the resultant economic and functional performance of the facility could be favourable or it could be unfavourable or even dangerous and remain so, knowingly or sometimes unknowingly, for many years of operation.

To achieve high standards of economic and functional performance requires a wide and thorough knowledge of engineering fundamentals and of the composition and behavioural characteristics of a large number of elemental and composite materials. In the mining industry these include reinforced concrete, ceramics, glasses, rubber, plastics, wood, mild steel, high carbon steel, low alloy steel, high alloy steels, stainless steels, nickel-chrome alloys, copper, brasses, bronzes, titanium, aluminium and various protective and insulating coatings in the form of paints, tapes, metals, and so on.

In the absence of a facility that could provide expert advice on the selection, use and protection of materials of construction, designs which are based on a limited knowledge of these requirements can only be of average standard. In addition to hidden costs, such a limited approach harbours a further danger by allowing the seeds of potential failure and destruction to be implanted in design details, weaknesses that could manifest themselves in breakdown of a minor nature or result in catastrophic failures with high cost to plant, production and human lives.

To quote an example outside the mining industry it will be remembered that the catastrophic failure of two Comet jets was traced back to a design weakness that promoted metal failure.

As a protection against potential break down of operating equipment recourse has been taken to the provision of stand-by equipment. Whilst this is admissible in certain cases of important equipment requiring regular inspection, the provision could be a wasteful expenditure of capital when the cause of such breakdown can be traced to design and materials inadequacies.

Although many examples could be given in support of the above observations, the following single instance should be of interest, as it illustrates the unnecessary expenditure of capital on equipment designed on the basis of an inadequate knowledge of the properties and fabrication of stainless steels.

The example concerns an investigation, presently being conducted, into the design of rotary filters in stainless steel for the filtration of acid slurries. The investigation has revealed that, in one particular instance at least, the design is an exact duplicate of the mild steel counterparts used for the filtration of alkaline gold plant slurries. This approach has ignored the superior qualities of stainless steel and fabricating techniques that promote its adoption.

A redesign of the agitator mechanism which has now been completed and costed has resulted in a technically more sophisticated structure that could be made and supplied at a price about three quarters of that of the old design.

Figure 11 and 12 show one detail of the design in which a costly and vulnerable procedure is replaced by a neatly fabricated shape.

Corrosion

Of all the deleterious influences to which the industry's materials resources are exposed, corrosion is perhaps the most pernicious and the most wide spread. It is a destructive force that manifests itself in a variety of forms with effects either readily noticeable, as for example general superficial corrosion of a metal surface, or completely hidden from sight as, for example, crevice corrosion in which the end result could be sudden or even catastrophic failure.

Fig. 11

Fig. 12

The scientific basis of corrosion in its various forms is well known and well documented. Its proper understanding, however, calls for an adequate knowledge of physical metallurgy and electrochemistry. For this knowledge to be of practical value in corrosion control, extension into the field of protection of equipment and engineering design would be important and essential prerequisites.

From a fair knowledge of conditions in the mining industry it is believed that many millions of unnecessary cents are still added to costs, annually, as a result of unchecked corrosion. Although, in certain instances, steps have been taken to apply a measure of consultative and supervisory control towards corrosion prevention, the need for a facility within the industry to supplement this service still remains an urgent necessity.

Conclusion

In a matter of only seven years gold production in South Africa will have reached its 100th year. The chances that this will in fact eventuate and, hopefully, extend well into the second century, will depend on the trend of the gold price, the cost structure and the gold, in situ, that will become available in terms of these controlling factors.

Whereas the gold price will remain an unpredictable entity, the success in maintaining the viability of the industry will therefore depend largely on the effective and productive use of its two major operating resources, namely its human and its materials and equipment resources. At present the costs of these resources are of much the same order, each being about R600 million per annum.

It is firmly believed that substantial improvements in costs can still be achieved by sophistication in the choice and utilisation of materials of construction and that, to this end, facilities should be established in parallel with those already in existence for the industry's human resources. From a reasonably fair knowledge of the present status of the industry it is estimated that savings of from 10 to 20 percent could, with time, be effected. In 1976 money terms this would average about R95 million per annum or R1,25 per ton milled. This saving would be exclusive of further savings in the associated maintenance and replacement labour.

By applying the approach of investigating, in each and every case, the reason for failure or discard, major changes in materials use and equipment design are visualized. An excellent example of this approach was the development by the South African Railways of the Scheffel bogie. This achievement, which no doubt will have far-reaching effects, was the result of two objectives, the one aimed at increasing the speed of trains and the other at eliminating the excessive wear on truck wheels that was experienced on iron ore trucks used on the Sishen-Port Elizabeth line.

A further example, but based on slightly different objectives, is what might be described as the down-to-earth spin-off of materials research in the aerospace programme. The need for a certain quality of stainless steel resulted in the development of an alloy with hardness, surface qualities and corrosion resistance that, fortuitously, became ideal for bone implants.

It is not inconceivable that the gold mining industry, bent on similar objectives and provided with a large field for the immediate testing of its innovations, could not come up with improvements that not only would benefit the industry itself but could spill over into mining and industry in general and even augment the country's exports. In this way a diminishing resource could generate a new resource in the form of technological innovation, charged with massive potential.

Greater sophistication in underground mining machinery and the processing of ores, as for example uranium, has called for superior materials and techniques to meet the new and, in certain cases, exacting requirements. It is becoming increasingly realised that no matter the merits of a new concept in the form of a machine or process, its translation into practice could be seriously hampered or even prevented by poor design or choice of materials of construction. In the case of new developments in process technology it is important that these should be supplemented, at laboratory and pilot plant stage, by a materials engineering facility, to take care of materials needs. Failure to do this could lead to costly repairs and replacements with long delays and serious loss of production. Without such a facility the approach to design of plant and equipment can never be regarded as truly professional.

WATER PROBLEMS IN MINERAL PROCESSING AND EXTRACTIVE METALLURGY

Numerous water-related problems are encountered in mineral processing and extractive metallurgy. Many have good solutions and so probably, "water-related challenges" might possibly be a more appropriate terminology. Several of these have been mentioned already. The most prominent water-related problems are those which result in a reduced recovery or selectivity of recovery due to the presence of contaminants in water. The contaminants may be present in the water supply or get into the process water due to contact with the ore, and in this latter case, may be enhanced due to water recycling.

Mineral Processing

Mineral processing refers to such processes as gravity concentration, flotation, wet magnetic separation, etc., i.e., mainly the physical separation processes.

Examples of water-related problems are:

- Reduced efficiency of flotation recovery of sulfide minerals at Rustenburg area platinum mines reputed to be due to high magnesium and other salts in the process water.

- The need to segregate water from one circuit to another when depressants are used, e.g., hexavalent chromium for galena depression in Pb-Cu separation. If the Cr^{VI} containing water is not segregated and finds it way into water recycled to the primary flotation process, then it will result in recovery losses in the primary bulk float stage.

- Oils, greases, and hydraulic fluids discharged or lost through leaks underground during mining can get into water and interfere in flotation recovery.

- Discharge of tailings from Umgaba sands ilmenite and rutile heavy mineral recovery operation in South Africa in the 1960's resulted in clay mineral pollution of bathing beaches.

- The need for additional gangue depressant doses when Ca and Mg levels in hard water build up as at Palabora Mining Company, Phalaborwa, South Africa, where copper and foskorite minerals are recovered from a carbonatite ore.

- Fluorspar flotation recovery is sensitive to water quality and deteriorates when water is recycled.

- Grinding and flotation circuits can generate thiosalts and thiosulfate which, if present in high enough quantities, makes it almost impossible to meet pH limits in receiving waters.

- When mine backfill using cement is used, calcium and other species in mine drainage can interfere with flotation recovery if used in the process water.

- In gravity concentration of gold (placer mining), recycled water can build up suspended solids levels and root fragments which can interfere with the recovery process.

- Sewage (either treated or untreated), if discharged into mill tailings and recycled with decant water to flotation plants, may or may not cause a recovery problem.

- Recycled water in complex sulfide flotation plants can build up dissolved metal levels due to oxidation of fine fragments of ore in the water or due to the presence of oxide ore in the feed. Dissolved copper in recycle solution cause a loss in selectivity in these circuits.

- Several reagents which, from a metallurgical point of view, are preferred may require special conditions or have to be avoided because of environmental problems when effluents are discharged (e.g., SO_2, NH_4OH, hexavalent chromium), or because of problems related to the emotional type of "environmentalist" (e.g., cyanide).

Extractive Metallurgy

A sampling of water-related challenges encountered in extractive metallurgy include:

- Cyanide-soluble base metals in gold and silver ores build up in recycled solutions until they interfere with the process and must be discharged as a barren bleed. Barren bleed contains a relatively high concentration of metals complexed with cyanide which represents a water loss, a cyanide and lime reagent loss, and presents an effluent treatment problem.

- Extraction of copper or zinc by hydrometallurgy results in jarosite formation which must be impounded to prevent a pollution problem.

- In acid leaching of uranium ores, tailing decant solutions cannot be recycled beyond a certain point because of the buildup of ions such as Cl^- which eventually make the solutions corrosive to stainless 314L steel and interfere with uranium recovery. At that point, discharge of an effluent or evaporation of the solution bleed is unavoidable. Depending on the climate, this may present a serious obstacle.

- When lixiviants are used to leach valuable eomponents from ore, more likely than not, other less than desirable species are leached too. For example, in uranium leaching, radium-226 and thorium, as well as selenium and other metals, are likely to

be leached as well. These present effluent treatment needs which add cost to an operation.

- Choice of lixiviant may be dictated as much by the cost of final effluent treatment as metallurgical process desirability.

- At least one uranium leaching operation is known (Agnew Lake) where the metallurgy would have indicated the use of solvent extraction, but environmental concern that organic solvents might harm a nearby trout steam resulted in the decision to use ion exchange.

- Recycling of solutions in several metallurgical processes results in the buildup of species in solution that one otherwise would not have been aware of, e.g., silica. Silica can cause fouling problems on ion exchange resins, filters, etc.

- The presence of metal cations in solutions can have an impact on recovery by recovery processes. For example, copper and nickel in solution can have a negative impact on gold and silver adsorption on carbon. Magnesium ions in a CIP pulp can affect gold adsorption, and so can bismuth.

- In order to secure a permit for most metal recovery operations, it is necessary to show in advance how damage to the environment will be avoided. To demonstrate that zero discharge can be achieved, a water balance for the total operation is required.

- To determine what, if any, effluent must be discharged, a salt balance may also have to be computed in advance. This presents a problem as metallurgical salt balance modelling skills and experience are still at a low point on the learning curve.

Mill Tailings Disposal

Mill tailings and mine waste containing sulfide minerals are the cause of the most serious environmental problems that face the mining industry and for which no complete answer has yet been demonstrated in practice.

Metallurgical and mineral processing waste disposal is under scrutiny at this time in several parts of the world most notably in Canada but also in the United States where the application of the Resource Conservation and Recovery Act (RCRA) to the mining industry is currently being debated. Although the Beville Amendment to RCRA regulations in the U.S.A. excludes mining and mineral processing wastes from RCRA, this inclusion is only temporary. Solid waste disposal and hazardous waste disposal rules will in one or another form be applied to mining and mineral processing waste in federal regulations which aim to protect surface and groundwater. Meanwhile, at the state level,

regulations very similar to the hazardous waste regulations of RCRA have been passed or are being proposed which will be applicable to mining and mineral processing wastes.

In South Africa, mineral processing wastes, i.e., tailings and wasterock, are being investigated to determine their impact on surface and groundwater and changes to the South African Water Act have been made that, if applied rigidly, could have very expensive consequences for some of the existing mining companies if it can be shown that they cause damage to water on land adjoining or beneath the operations. Although actual fines are not too severe, the law makes provision for compensation to neighbors that suffer damages as a result of water pollution and forfeiture of profits by a company that pollutes water on adjacent property or groundwater beneath the operations.

Mill tailing impoundment designs are evolving along with environmental protection awareness. Some of these, when applied in conjunction with tailings which have certain physical and chemical properties, may result in tailings which have extremely low permeabilities and which, therefore, effectively encapsulate contaminants.

Perhaps the most important of these is the "sub-aerial" or "semi-dry tailings" system of Knight and Piesold, also used in Steffen Robertson & Kirsten-designed impoundments. This method and others are described in a separate chapter later in this report, and are more appropriate in areas with drier climates and net evaporation. CANMET in Canada has conducted experiments which hold promise for prevention of AMD from tailings in wetter climates which rely on special vegetation cover applications.

There are several problems and challenges relating to mill tailings disposal:

1) Mill tailings for modern mine-mill complexes can involve very large tonnages of material. The Witwatersrand and Orange Free State gold and uranium mining industry alone in 1978 disposed of 78 million tons of tailings, almost all to above-ground "slimes dams." These are by no means the only large volume sulfide containing tailings in the world.

2) Often, mill tailings contain unoxidized sulfide minerals, e.g., pyrite, pyrrhotite, and marcasite. These tend to oxidize over a period of time and yield acid mine drainage, probably the most serious problem facing the mining industry today.

3) The prospect of "perpetual" treatment of acid mine drainage collected from tailings disposal areas and the need to manage tailings disposal sites for the next 300-400 years or longer presents a significant problem to the mining and mineral processing industry.

4) Mill tailings are generated at mine-mill locations, and often there are not all that many options for tailing disposal sites at some of them.

5) Mill tailings are prone to dusting, and wind-blown tailings distributed from the site can result in an even widerspread acid mine drainage problem. This means that if water quaiity protection is to be achieved, then especially sulfide-containing tailings must be disposed of in such a way that prevents wind erosion and distribution of the material beyond the managed impoundment area.

6) Some states are calling for double linings of tailings impoundment areas regardless of the cost-benefits of installing them. This presents a cost problem in some cases.

7) Disposal of wet tailings in impoundments ties up a large volume of water.

There are several emerging and improved technologies which avoid or overcome these and other problems which are described in later chapters, but the fundamental mechanisms of generation of AMD in sulfide-bearing tailings and how to avoid it are not yet understood.

Reagent Storage and Spills

Mining, and especially mineral processing operations, employ a long list of reagents, surfactants, and other reactive materials. Some of these are corrosive or toxic; others flamable, while many in small doses are unlikely to harm the environment.

Reagent transportation, storage, and spill control is an area of increasing concern for existing mining and milling operations as well as new ones.

In some parts of the U.S.A., transportation of reagents to a millsite is specifically not permitted during certain times of the year.

Reagent spills must be reported and would be subject in many cases to punitive action in the U.S.A. In new mill designs, chemical storage areas require berms--often lined--to catch any accidental spills.

Hazardous reagents are often used, e.g., chlorine, cyanide, $BaCl_2$, and special safe handling storage procedures and facilities are required.

Reagent transportation, storage, and spill control would seldom be a problem when the operators are properly equipped and trained and when the facilities are intelligently designed to contain such spills.

Recent groundwater quality awareness has brought to the surface the problem of underground storage tank leaks, particularly gasoline and fuel tanks. Underground storage tanks, particularly at older operations, can leak and present a serious contamination problem, but no more so than the neighborhood gas station in most cases.

Boiler Water

Many mineral processing and metallurgical operations employ boilers to generate steam. Boiler feed water used should be soft and as low in TDS as possible to avoid scale formation on the heat exchanger tubes.

This very often requires that demineralized water be used when the local well, stream, or lake water TDS is high.

When boiler feed water must be demineralized, this is generally done by a lime-soda softening process followed by dual-bed ion exchange demineralizers.

Apart from the cost, demineralizer systems produce a concentrated salt solution which must be disposed of.

Potable and Service Water for Mines and Mills

Potable water is required for the mine and mill operators and also at change houses for the maintenance staff as well as at mine housing.

The quality of water available at mines and mills may be poor where a regional water supply is not laid on. Sometimes, this presents a problem which calls for a costly solution.

Examples of this include the Rooiberg Tin Mines operation where the only available water is from one of the mineshafts, and it contains fluoride well in excess of the maximum permissable level for drinking water. The company has had to install two defluoridation plants and a pumping/piping system linking both their mines at a cost in the milling range. This a major expenditure for a small mining company.

All water delivered to underground workings in South African mines must be disinfected to render it drinkable. African mineworkers have a habit of drinking water where they find it regardless of instructions, and the disinfection requirement is a safety measure to prevent virus or bacterial infections.

Disposal of Contaminants

Many mineral processing operations generate contaminated effluents. So would desalination units in effluent treatment plants. All of these must be contained and/or disposed of.

When a large stream of water is treated to remove contaminants, e.g., dissolved metals, a smaller, but appreciable volume of precipitate sludge is generated. Often, a toxic waste is generated from a non-toxic waste, and this can present special disposal problems of its own if the legal requirements are to be met. There are innovative ways to achieve this, but this can also present a problem, see Chapter 21. Sometimes this consideration is the deciding factor in selecting one type of effluent treatment process over another.

CHAPTER 5

WATER RECYCLING IN METALLURGICAL PLANTS

CONCLUSIONS

1) The incentive to recycle water may be to meet the zero discharge permit requirement or because fresh water is not available in adequate amounts, or only a excessively high cost.

2) The minimum amount of water required in a mineral processing plant seems to be proportional to the amount available.

3) Considerable water savings can be achieved, for example, in acid uranium leaching when there is no alternative, but there are significant costs involved both in measures to counteract corrosion and abrasion, as well as in recovery and plant throughput.

4) Sulfide mineral flotation recovery operations vary from simple straightforward flowsheets to complex sensitive operations with numerous interdependent circuits. Water can be recycled in these but, in several circuits, recovery losses or deterioration in concentrate grades result. To date, the reason for these phenomena are not fully understood, and much more fundamental work will be needed before the mechanisms for these empirically-based phenomena are explained and counter measures found. Some circuits are more sensitive than others and, at one complex sulfide plant, recycled water constitutes 80% of the water used with only 0.55 m^3 fresh water used per ton ore.

5) Research work by Brunswick Mining and Smelting and Lakefield Research is believed to have indicated a process arrangement that uses a higher percentage of recycled water than was possible before.

6) Recycling of water results in changes in water quality as dissolved salts build up in solution. Prediction of these changes for an integrated multi-component plant through water balance and salt balance modelling is, at this stage, an emerging and as yet imprecise skill.

7) Buildup of dissolved salts in recycled solutions result in interferences with processes such as filters and clarifiers for solution polishing, for example, as required ahead of solvent extraction of uranium from acid solutions. Building of dissolved solids in tailings solutions due to water recycling can also introduce problems such as scaling up of tailings pond underdrains. These are problems that will occur more often due

to increasing use of more efficient solution recycling in metallurgical operations and for which better and more routine answers are needed.

The RANDOL investigation asked six questions at every operation that was visited over the last 18 months:

- How much net water does your operation consume?
- What is the quality of your water, and what effect does this have on your process?
- How much water do you recycle, and where in the circuit?
- What effect on water quality and on metallurgical recovery does recycling have?
- How much water can you recycle, if necessary, without running into metallurgical or other problems?
- Is water treatment used or needed to make recycled water more usable?
- Are your tailings pond, water storage impoundments, etc. lined, i.e., are there salt bleeds? Is solution reclaimed from the tailings pond via decantation, underdrains, or seepage cutoff trench collection?

Most often, the RANDOL inquiry was referred to an environmental engineer to answer questions about water. Very seldom were these staff members able to respond to questions about metallurgical effects of recycling. This is an example of the need for a "systems approach" to this important aspect of water management.

HOW WATER IS RECYCLED

Water can be recycled in several ways. For example, tailings decant solution may be the main water supply to the mill with fresh water added either to the return solution reservoir or directly to specific circuits in the plant.

In some cases, recycle solution is drawn from the tailings pond directly by decantation or through underdrains, or it may be pumped to an ageing pond prior to reuse. There are several possible arrangements in which water can be recycled within a mine-mill complex. These are illustrated schematically below.

In operations that recycle tailings solution, this can be through decantation directly from the tailings dam or seepage collection via cutoff trenches. When seepage is collected and recycled, its quality may be significantly different to the solution recycled directly from

the pond--very often the seepage will be much lower in TDS as some degree of natural purification often occurs while the seepage is in contact with soil or rocks.

Some metallurgical operations recycle solution internally. For example, consider a conventional Witwatersrand gold mill that segregates fresh mill water, then recycles cyanide-bearing barren solution back to the leaching circuit, and finally recirculates tailings pond water which is used to repulp filtered tailings.

DIRECT RECYCLE

RECYCLE AGEING

RECYCLE AGEING & EQUILIBRATION

RECYCLE TREATMENT

MACRO-RECYCLE

PERCENT RECYCLE VS. NET WATER CONSUMPTION

It is customary in many metallurgical operations to report the percent water recycle used. It is important to distinguish between percent recycle water used and net water consumption.

For example, in one operation using 1.0 m^3 fresh water per ton ore treated combined with 3.0 m^3 recycled water per ton ore is using 75% recycled water. A second operation consuming 0.8 m^3 net fresh water per ton ore combined with 1.6 m^3 recycled water is using only 66% recycled water, but it is in fact using less fresh water and discharging a smaller volume of effluent.

Percent recycle water used in the operation does not reflect how water efficient an operation is.

INCENTIVE FOR RECYCLING

Most metallurgical operations have set an objective to use as much recycle water as possible. Some do not recycle any water. The incentives of those that do recycle water may be quite different on a case-by-case basis. The most common incentives to recycle water are:

- Water conservaton; to reduce net water use.
- Reagent conservation.
- To minimize the volume of effluent to be treated or discharged.
- To meet zero discharge requirements of the operating permit.

EXAMPLES OF WATER RECYCLING

Rössing Uranium Ltd.

Rössing Uranium Ltd. has reduced their 1984 net water consumption for an acid uranium leach to 0.4 m^3/t ore which is a remarkable achievement, even though their consumption may increase again once the water level in their tailings pond has been lowered to the planned level. By comparison, the QUIVIRA MINING COMPANY at Ambrosia Lake, New Mexico, which also recovered uranium by acid leaching using a similar process, consumed 1.75-2.4 m^3 fresh water per ton ore treated depending on plant throughput which is typical of water consumption by uranium mills that have less need to recycle water.

Rössing Uranium achieves this low water consumption at the expense of metallurgical efficiency in the ion exchange plant, but because so much of their solution is recycled, some of the uranium not recovered the first time around is recovered later as the water recycles. Using water with a much higher TDS including $SO_4^=$ and Cl^- results in competition for adsorption sites on the ion exchange resins employed. There are also enhanced corrosion and scale effects. These are all discussed in the trip report on Rössing Uranium in Appendix I. CIX is employed for primary uranium recovery in both the main plant and at a plant treating reclaimed tailing solution.

Nowhere else in the world has such an immense effort been made to cut down on net water intake at an acid leach uranium mill. The composition of seepage collected below the tailings dam indicates that during seepage, several contaminant levels are significantly reduced. The effect of recycled water quality is discussed in the following correspondence from Rössing Uranium Ltd., and more information may be available from:

RÖSSING URANIUM LTD.
Post Office Box 22391
Windhoek 9000
South West Africa/Namibia
(061) 36760
Peter N. Vernon,
Technical Controler

RÖSSING URANIUM LTD.. reduced their water consumption from 30,000 m^3/d to 14,000 m^3/d. Because RÖSSING uranium ore is relatively low grade, the concentration of uranium in solution is reasonably low, within the realm of applicability of continuous ion exchange recovery as opposed to SX which is more cost-effective for more concentrated solutions. CIX systems are not as vulnerable to suspended solids levels in the pregnant solution as SX, consequently, the need for multi-media filtration to polish pregnant solution ahead of recovery is avoided.

2nd May 1984

Mr. H. von Michaelis,
Randol International Ltd.,
21578 Mountsfield Drive,
GOLDEN, COLORADO 80401.
U.S.A

Dear Hans,

Sometime ago you asked for information regarding the effect of increased TDS on Ion Exchange performance.

I attach hereto, a copy of a memorandum from Steve Kesler to myself that I think gives you a fair picture of the effect of high TDS water being used in the Metallurgical Plant as a whole.

The only point that I would add myself is that, although we can certainly cope while we are on a slightly reduced production level due to the present state of the Uranium market if we were striving for every ounce throughput, Ion Exchange capacity would in my opinion be a constraint on our performance.

Yours sincerely,

P.N. VERNON

CIX info for Randol

At present we are recycling about 60% RDS and 25% seepage into the rodmills. The recycle water has a TDS of about 50 000ppm with 30 000ppm sulphate and 1 300ppm chloride. This compares to the analysis of fresh water at 900ppm TDS, 35ppm sulphate and 280ppm chloride. It is obvious therefore that with this rate of water recycle there will be a build up of TDS in the pregnant solution circuit.

At present the sulphate concentrate in pregnant solution to CIX is 35 000ppm whilst chlorides are about 1 300ppm. These figures compare to sulphate levels of 25 000ppm and chloride levels of 600ppm prior to water recycling.

Considerable test work has been carried out in the laboratories to determine the effect of increased levels of sulphate and chloride on the ion exchange plant performance. Both sulphate and chloride are competitive ions to uranium for exchange sites on the resin. Test work has indicated that a 10 000ppm increase in sulphate level would increase the CIX barrens by about 4ppm. Similarly a 1 000ppm increase in chloride concentration would increase barrens by about 1,5ppm. However, in practice on the plant we have not had an increase in barrens due to water recycling because of modifications made to the elution sequence. In order to overcome the deleterious effect of water recycling, the resin transfer rate has been increased by increasing the elution frequency from 30 elutions per day to 35 elutions per day.

A computer model of the plant indicates that eventually an equilibrium situation will exist whereby sulphate levels and chloride elvels in the pregnant solution will stabilise at about 40 000ppm and 1 600ppm respectively.

Before the recycle programme commenced, the ion exchange plant capacity was increased somewhat by the addition of an extra absorption stage to each CIX line.

The other major deleterious effect of the water recycling programme has been the increased incidence of precipitation of scale in the plant. This is particularly noticed at solution/air interfaces and the scale has been identified as predominantly jarosite but with appreciable calcium sulphate. There are indications that the precipitation of jarosite has also been associated with the introduction of a ferric leach plant and due to some microbiological activity. The scale results in some plant nuisance and of course increased operator activity. The formation of a rough jarosite scale

within the barren pipeline has been the most problematical scale to remove. However, tests had been undertaken with polypropylene pigs which appear to remove the scale satisfactorily in about three passes. It is planned to purchase these pigs and to run them through the barren line during normal operations on a regular basis.

Within the reduction plant extensive use is made of 316L stainless steel, i.e. for thickener rakes. With increased water recycle we have encountered formation of jarosite on the rakes and beneath the jarosite the onset of pitting corrosion. Crevice corrosion has also been noted behind nuts etc. After some experimentation four thickeners have now been coated with polyurethane after sandblasting to obtain a satisfactory surface for bonding. To date our experience leads us to think that urethane coating will be a satisfactory solution for corrosion protection of these rakes. Although water recycling is not without its problems, the benefits far outweigh the problems which are not insurmountable.

S B KESLER

New Mexico Uranium Operations

The uranium operations in New Mexico are also located in a very arid climate around Grants, New Mexico. It was expected that these would also have to recycle a lot of water because of limited supply. This is not the case. At QUIVIRA MINING, excess minewater is treated to remove uranium by ion exchange and radium by $BaCl_2$ addition and settling before being discharged to the desert.

Of about 3,500 m^3/d water that goes to the tailings pond daily with tailings, only 1,022 m^3/d is returned for recycle and, indeed, the only reason and need to recycle solutions is to avoid having to construct additional costly lined evaporation ponds. Composition of process water at this Ambrosia Lake operation is as follows:

TDS	2,286 ppm
Hardness	900
Ca	200
Mg	80
Na	300
SO_4	1,300
Cl	113
U_3O_8	2.3
Se	0.2
Mo	.75
Si	Less than 10

The QUIVIRA MINING CORP. would like to recycle more water from the tailings plant to reduce the amount to be evaporated still further, but the limiting factors are lower recovery by SX and the enhanced corrosion of the CCD thickener parts made of stainless steel which would not stand up to the 1,300 ppm Cl^- level at pH 1.2 of pregnant solution. If water was a real economic factor, however, it would be possible to coat the stainless steel with polyurethane as has been done at Rössing. Another factor to consider if more water were to be recycled is the buildup of TDS which could also result in cementing of media in the multimedia polishing filters ahead of the SX plant which would be more prone to scaling up.

MACRO RECYCLE AND EFFECTS

Because of widespread seepage of high TDS tailings solutions into underground working, there has been a steady change in the quality of underground water pumped from the Ambrosia Lake mines amounting to the effects of a macor recirculation of water from underground. The minewater delivered to the CIX plant near the mill now contains 2,800 ppm TDS, including 1,600 ppm $SO_4^=$ and 150 ppm Cl^-. Under these conditions, uranium

which is present at 10-12 ppm loads onto resin at only 0.6 lb/ft^2 (10 g/l) before breakthrough occurs compared with a loading of 2 lbs. U_3O_8/ft^3 at the second CIX plant serving mines 35 and 36 further away from the tailings where TDS in minewater is lower.

The result of the change in water quality and increase in competing ion concentration in the CIX process has been to require an increase in elution cycles from 16 per month to over 100. Resin inventory has had to be increased as well to keep the U_3O_8 level in the CIX treated water at below 2 ppm U_3O_8 for discharge. This has required a much greater load on the elution plant and a correspondingly greater cost of reagents consumed with no increase in uranium recovery.

IN SITU LEACH

The very nature of in-situ leaching implies striving for optimal recovery and recycling of solutions and lixiviant values. Reagents are added to solutions which are pumped underground under pressure where uranium is leached, and uranium values are then recovered, usually by CIX from the pregnant solutions.

Recycling of solutions is likely to build up competing ions as well, but it is not know what specific effects these have on the metallurgical process.

Certainly, great care must be taken to avoid the use of Na salts in the reagents where there are smectite clays in the leachfield. Replacement of calcium by sodium in clays causes them to swell resulting in a marked decrease in porosity. If, through recirculation of solutions, Na could be replaced by calcium on the other hand, then there would be the possibility of improving the porosity of the leachfield.

WATER RECYCLING IN BASE METAL FLOTATION PLANTS

There is a wide discrepancy in the amount of water that can be recycled from one base metal flotation plant to another. Factors that influence water quality effects on flotation chemistry are not quantitatively known. Whether or not a mill superintendent will use a particular stream of recycled water in a particular circuit often depends on the way he feels about rather than on hard fact. Even when a water stream has been found to result in a reduction in metallurgical efficiency, the reasons are seldom known but gives rise to guessing. The result is a dearth of knowledge of what steps could be taken to correct the problem and make the water usable. This is an area that was recently being examined in some detail by NORANDA MINES LTD. Some comments and characteristics of water recycling and recycling effects at base metal flotation plants are listed below.

Cu-Pb-Zn Mill G, Ontario

This 3,850 stpd mine recovers a copper, lead-silver, and zinc-silver concentrate from a massive sulfide orebody. The tailings contain an average of 20% pyrite. Ammonia is used for pH adjustment in the plant because of the ease of handling and because after addition of freight costs, it is the most economical reagent. Lime is used in the effluent treatment plant.

Of all the flotation plants visited, this operation recycles a greater percent of its total water needs from tailings amounting to 80%. This mill has been working on improving its water recycling program since 1972. Their objective is to achieve 85% recycle.

Water to the mill concentrator plant is made up as follows:

Fresh Lake Water	184.51 mm I gal/yr	1,929 m^3/d	0.55 $m/^3t$
Water in Ore Feed	7.30 mm I gal/yr	77 m^3/d	
Lake Potable H_2O	1.92 mm I gal/yr	22 m^3/d	
Recycle Water	594.6 mm I gal/yr	6,210 m^3/d	1.77 m^3/t
TOTAL	788.33 mm I gal/yr	8,244 m^3/d	

0.6 m^3 new water per ton ore feed is used, excluding potable water and water contained in ore feed. Overall water used is 2.55 m^3/mt including potable and fire fighting service needs.

- When recycled tailings water which is saturated with $SO_4^=$ was used for reagent mining, it was observed that when ammonia and cyanide reagents were used in the plant, that severe scaling resulted in the reagent system, and reagent feed control was impossible. As a result, the mill switched to fresh lake water for this function.

- SO_2 and ammonia are mixed to form $(NH_4)_2\ SO_3$ before addition to the rod mill to depress zinc in the bulk Cu-Pb-Ag flotation step.

- Recycle water, even though ore is milled in an alkaline pH, contains only about 100 ppm thiosulfate which is lower than in some other operations. This is ascribed to lower reactivity of the sulfides in the ore.

- Cemented tailing backfill is employed underground. Sometimes cemented backfill fragments get into the ore, and this appears to result in a reduction of selectivity in the copper rougher circuit. Tests in the lab confirmed that when cured backfill gets into the ore, both copper recovery and selectivity are affected, i.e., zinc appears in the copper concentrate. Copper concentrate grade can drop.

- Attempts to correlate calcium in the rod mill discharge with Cu recovery and grade were inconclusive.

- At times of selectivity problems in the plant, it was found that soluble copper concentrations in the process solutions had increased from 6 ppm to 11 ppm which might be significant and realted to water recycling.

- Fresh water is used in pump glands and for the Cu-Pb separation step. Separation is impaired when recycle water is used as launder water for the Pb-Cu concentrate and onwards. Operators are not certain what species present in the recycle water affects the Cu-Pb separation.

  With fresh water, a lead concentrate of 65-70% can be achieved by depressing Cu with cyanide. With recycled water, the lead concentrate grade reaches 50% with difficulty. It is possible that sulfate or something else in the recycle water affects lead concentrate flotation performance.

- Tailings pond rec'aim water at this operation is found to be too scaling for a lamella thickener to be used after treatment by lime addition. A convntional thickener is used.

Cu-Pb-Zn-Ag Mill M, Ontario

This mill in Ontario was designed to treat 3,000 stpd. A high pyrite variable underground massive sulfide orebody with up to 40% sulfide is mined at one site. The second open pit ore contains 25-30% pyrite.

Cu, Pb, Zn, and Ag are recovered in three concentrates by floating a copper-lead-silver concentrate first. This is then separated to make a copper concentrate by depressing lead with quar gum and SO_2, and whatever zinc may have carried over with the Cu-Pb. SO_2 helps Cu to float. Zinc is floated from the primary flotation tails.

Soda ash is used for the Cu-Pb bulk flotation circuit which is operated at pH 9-9.5. Sometimes, some SO_2 is used in the rod mill when the ore is not "clean." The zinc can be quite oxidized in some of the ore feed.

As in the previous case, recycle water is found to result in a lower grade concentrate if it is used in the Cu-Pb separation step. Fresh water is used for flotation of a copper concentrate from the Cu-Pb concentrate.

At the time of the Randol visit, fresh water was added to the rod mill with Na_2CO_3 and SO_2 reagent and to the ball mill. Recycle water, if used in the ball mill, results in a

higher zinc content in the Cu-Pb bulk concentrate. This might be due to activation of sphalerite by low levels of dissolved copper in the recycle water.

Recycle water is used without problems for zinc flotation from the primary flotation tailings.

Ore is ground at an alkaline pH around 8.5 so thiosalts are generated. The staff believes that thiosulfate levels are around 70-80 ppm in winter and higher in summer.

Too much collector added at the front end of the circuit ruins the selectivity of the first semi-bulk flotation. Consequently, the plant is run on "starvation" amounts of collector. This keeps Zn out of the Cu-Pb concentrate but results in a slightly reduced Cu-Pb recovery. Because recycle solutions are used in the primary flotation step, care must also be taken that collector does not recycle to the front end of the circuit.

Activated carbon is added to adsorb any extraneous collectors that may be present before the Pb-Cu separation step.

	ppm Zn	ppm Fe	ppm S_2O_3	ppm S/S	pH	ppm Cu

° Lime is added to reclaim water and allowed to settle in a pond. pH must be increased, or it would corrode the steel line.

Cu-Mo Porphyry Operations in the Southwest U.S.A.

Somewhat sketchy information was gathered about water recycle at copper molybdenum flotation recovery operations from porphyry ore deposits in the desert southwest, U.S.A.

Water is recycled in the copper-moly flotation circuit in most instances, but almost never in the copper-moly separation step.

In almost al cases, no recycle water is used in the moly separation plant which is usually the point at which fresh water is added to the complex. However, at Phelps Dodge, Morenci plant, which uses ferrocyanide as a depressant instead of the conventional NaHS, recycle water is used. This is a new development, the plant having relatively recently changed over from fresh water for this application. So far, there has been no drop in recovery or grade according to:

EFFECT OF FRESH WATER INCREASE AND IMPROVED WATER QUALITY

Black Mountain Mineral Development Company Limited

South American Copper-Molybdenum Producers

It is known that high TDS, poor quality water is used at some of the South American copper-moly producers. At the sulfide flotation operation at CODELCO's Chuquiquamata operations, it is believed that poor-quality recycle water is used, and that every possible source of secondary water and recycle water must be used. A reply to RANDOL's request for more information on this aspect is still awaited.

EXXON Crandon

The EXXON MINERALS CORP. planned operation at Crandon, Wisconsin, which will recover copper, lead, and zinc concentrations from a complex sulfide ore deposit, will be the first zero discharge operaton in a climatic region with net precipitation. It is too soon to tell what impact recycling of reclaimed tailings solution will have on the operation, although a general discussion on water recycling and treatment for new complex sulfide treatment plants was presented at the Randol Water Workshop at Beaver, Creek, Colorado, in October, 1984. Details on how water will be managed at Crandon have not yet been published.

Swedish Complex Sulfide Plants

Swedish companies, in particular BOLIDEN AB, have undertaken significant development research to define the effects of recycling water in complex sulfide flotation plants. Papers by FOSSBERG, et al. (1984) and BROMAN (?) are inserted in Chapter 54.

Black Mountain

BLACK MOUNTAIN MINERAL DEVELOPMENT (PTY) LTD. operates a Cu-Pb-Zn-Ag flotation plant near Aggeneys in Namaqualand, South Africa. This operation employs three main flotation circuits with nine different flotation reagents being added at up to 43 points. Lead and zinc flotation recoveries achieved their targets, but there were problems in achieving a satisfactory copper recovery.

Apart from initial problems of oil and grease getting in the ore, it has been found that disssolved oxygen levels are critical. Aeration of solutions was found to help considerably and also the use of dichromate to depress galena in the copper cleaner circuit. An excellent account of the complex tests and development work in the improvement of this complicated flotation plant has been given by TWIDLE and ENGLEBRECHT (1984). Additional information will be presented by TWIDLE, et al. (1985).

Data provided by the Black Mountain staff shows clearly that recovery of lead in their process is impaired by the use of more recycled water or, conversely, that it is improved by the use of more fresh water.

The Black Mountain flotation circuit arrangement and sequence is different to that used in massive sulfide treatment plants in Ontario and New Brunswick--probably because the Pb:Cu ratio is so much higher at Black Mountain which may require a different route and reagent selection. The Black Mountain flowsheet applies selective flotation of copper, then lead, and then zinc.

The backfill with cement, introducing calcium into the ore and water, seems to cause some detrimental effects on flotation as observed at INCO's Thompson plant and possibly at NORANDA's Geco operations. Data collected on Black Mountain is reviewed in a trip report in Appendix I.

Makeup water consumption at several copper and copper molybdenum operations is as follows:

Operation	Makeup Water at Full Capacity	Makeup Water at Partial Capacity	Gross Water Use per t Ore	% Recycle
Duval, Sierrita	217 U.S. gpt (0.82)	225 U.S. gpt (0.85 m^3/t) at 75% Capacity	-	-

Foskor Ltd., Phalaborwa, South Africa

Foskor treats ore from two sources:

1) 25,000 TPD tailings from the PHALABORWA MINING CO. after PMC has removed the sulfide minerals by flotation. Foskor recovers apatite baddeleyite and magnetite. This "ore" is received at 50% solids, i.e., with 25,000 m^3/d water from PMC's circuit.

2) A further 25,000 TPD from a PMC ore stockpile which FOSKOR mills and floats to recover copper which is sent as a concentrate to the PHALABORWA MINING COMPANY. Then, phosphate minerals are recovered and, finally, baddeleyite is recovered by gravity.

Foskor discharges 20,000 m^3/d of water effluent to the Olifants River.

The 25,000 TPD flotation tailings transferred from PMC is accompanied by highly contaminated water containing F^-, Ca^{2+}, Mg^{2+}, SO_4^{2-}, $SO_3^=$, Cl^-, and Na. It has a TDS of around 5,000 ppm and 4 ppm F. Calcium and magnesium combined average 2,500 ppm.

The hardness of the water reacts with the fatty acids used in the flotation recovery of apatite and forms Ca and Mg oleates which are insoluble soaps and form a scum in the froth. As a result, excessive reagents are consumed.

In one circuit, poly glycol ether is used; in another circuit, poly glycol ether combined with a modified polysaccharide is used.

The chemically modified polysaccharide is made from quar beans in South Africa by TROCHEM (PTY) LTD. and is known by its trade name, ACROL LG21 and LG31.

The FOSKOR flowsheet and water balance is included in a trip report on the operation with a discussion of their water recycle and the effects thereof. The quality of the water in FOSKOR's circuits is a direct result of recycling of water at PMC which is then bled to FOSKOR with PMC tailings at 50% solids.

The cost of gangue depressants amounts to "millions of Rands" annually. A test using 50% fresh water with 50% recycled water failed to yield a big reduction in reagent needs.

In FOSKOR's case, the low price of water is not a deterent to using more water. Availability of water may be threatened by periodic droughts. A likely need for recycling is availability of supply.

FLUORSPAR FLOTATON

Martin Wilson of the U.S. BORAX AND CHEMICAL CORP. was awarded U.S. Patent 4248708 dated February 3, 1981, which provided an improved process for treating water obtained from a fluorspar flotation procedure which substantially reduces slimes and interferring soluble materials, allowing the water to be recycled in the process and also improving its quality to make it suitable for discharge to the environment.

The process refers to a specific combination of coagulants and flocculants to obtain a clear water for recycle without adverse affects on fluorspar recovery allowing recycle of in excess of 90% treated process water.

The reagents used are a combination of cationic polygalactomannan derivative as primary flocculant and a high molecular weight polyethylene oxide as a secondary flocculant. The polyglactomannans are polysaccharides composed of galacton and mannose units, usually found in the endosperm of leguminous seeds such as sugar, locust bean, honey locust, flametree, etc. The derivatives of use here are cationic. A copy of the patent is inserted into Chapter 54.

LEAD-COPPER SEPARATION USING HEXAVALENT CHROMIUM DEPRESSANT

Hexavalent chromium is a potent depressant of galena, even in very small quantities, and is commonly used for separation of galena from copper-lead bulk flotation concentrates.

Because of the toxicity of hexavalent chromium solutions, tailings containing this ion must be very carefully segregated and treated before discharge. If water used in the lead-copper separation step is not kept completely separate, there is the danger that it may get into the main recycle solution stream. Even traces of hexavalent chromium in the primary flotation circuit will cause a reduction in galena recovery.

Thiosulfate ions will reduce hexavalent chromium to trivalent chromium, but it would probably be dangerous to rely on this happening quantitatively in the tailings dam. This certainly did not happen at the NEWMONT MINING COMPANY's Idarado Mill near Telluride.

At the Missouri lead belt, dichromate is used for copper/lead separation. Water from this circuit is always kept separate except at the Magmont Mill where only 25 percent water is

recycled. In the early days of operations in the Missouri lead belt, deleterious results were experienced, possibly because of inadequate separation of dichromate-containing solutions.

It is concluded that if dichromate reagents are to be used in sulfide mineral flotation, then that part of the process and all water used should be kept completely separate from the rest of the plant.

Additional insight into this problem may possibly be available from:

GOLD AND SILVER HEAP LEACHING

Heap leaching typically requires 0.004 gpm/ft^2-0.007 gpm/ft^2 (0.21 m^3/m^2/d-0.4 m^3/m^2/d) solution application. Efficient solution recovery and recycling is a funadmantal aspect of the process.

Solutions are usually spray irrigated onto the heaps which are often located in extremely arid climates with hot summers where evaporation rates are high. All solutions recovered from the lined heaps are recycled via a pregnant solution pond, metal recovery plant, and barren solutions pond.

Net water consumption in heap leaching can be as low as 0.2 m^3/t leached average for the year but will be higher than this average in summer. In winter, there can be a net gain in solution due to precipitation.

Some operations recover gold and silver by zinc precipitation; others use carbon adsorption. Zinc precipitation continuously adds zinc to the solutions. The addition of hydroxides, usually lime but in some cases NaOH or Na_2CO_3, adds to the TDS load of the recirculating solutions.

An interesting observation made at Tombstone Exploration, Inc., Tombstone, Arizona, is that despite the addition of 31 g Zn/m^3 solution on each pass, zinc levels build up to an equilibrium point and then stabilizes at a relatively low level in the "off" solution.

Recirculation of solutions, evaporation, and reagent addition does result in a TDS accumulation in heap leaching solutions. There is evidence that some dissolved salts drop out in the heaps, but the solutions can become scaling, and this could be expected to result in severe metallurgical problems due to fouling of carbon in columns or filters, pipelines, sprinklers, and the heaps themselves. Some plants have a much more serious scale problem than others due to water quality differences.

When fresh water is added to recycled solutions in metallurgical circuits, operators have noted that scale buildup seems to occur close to where the fresh water was added. An innovative way of reducing scale problems is implemented at one operation where the fresh water is mixed with recycle tailings solution in the "on" solution pond. Precipitate is allowed to form and to settle out before the solution reaches the heap or process.

Virtually all heap leaching operations for gold and silver use some form of scale inhibition. Examples are:

Operation	Reagent	Dose
Tombstone Exploration, AZ	NL Industries Barochem 535	--
Candalaria, NV	Drew Millsperse 802	50 cc/Min.
Cortez Gold Mine	Drew Millsperse 802	2-5 ppm

In Western Australia, available groundwater can contain 10,000 mg/l TDS and more, and yet is is used successfully in heap leaching projects.

Some operations experience more severe water problems than others. In the Mojave Desert, California, several small heap leaching operations were unsuccessful, reputedly due to the very poor water quality that interferred with the process. One company, AMERICAN MINE OPERATORS in Amboy, California, successfully heap leaches with a saturated calcium chloride solution which precipitates $CaCl_2$ crystals along the drainage ditches. More information about how success is achieved with such high TDS water may be available from their consultant:

COUNTER-CURRENT HEAP LEACHING

Research efforts are underway to develop a counter-current heap leaching process to generate pregnant solutions that have high enough gold and silver values for direct electrowinning. The stability of gold and silver in solution when in contact with ore on the heaps is an important aspect that has yet to be resolved, and it is likely to vary from case to case. This technology is the special study area of:

Judy Eisele

Charles Escapule of the small state of Maine heap leaching operation in Tombstone, Arizona, observed that silver could be leached relatively easily from ore the first time around but that if it were allowed to precipitate back on the ore in the heap, dissolution was very much more difficult the second time around.

VAT LEACHING, AUSTRALIA

GRANTS PATCH PARTNERS in Australia uses whatever water is available for leaching gold from old tailings in vats followed by carbon adsorption. Their experience is that when copper and nickel concentrations get too high in the recycle solution, such a method loses its viability. They are, however, able to use water with up to 10,000 mg/l TDS which is often high in aluminum and requires large additions of lime to reach pH 9.5 used in cyanidation. Water quality has a significant impact on carbon recovery of gold from solution and on the cost of reagents used.

In this case, an added benefit of recycling solutions efficiently is that much smaller amounts of reagent are needed than if new high-TDS water were used each cycle.

CYANIDE SOLUBLE BASE METALS IN GOLD AND SILVER ORES

Water recycling is standard practice in gold and silver recovery using cyanidation. By recycling solutions, water is conserved and, particularly, lime and cyanide consumption reduced.

When gold and silver are cyanide leached from ores containing cyanide soluble base metals, these base metals also leach and accumulate in the recirculated barren solutions until they reach levels that interfere with both gold dissolution and zinc precipitation.

This is commonly experienced in gold operations treating ores with high base metal contents, e.g., Cu, Ni, Sb, As, etc., as occurs in western Australia, eastern Transvaal, and several operations on the Canadian Shield.

To overcome the problem, a barren bleed is necessary. The volume of barren bleed can exceed 50% of the fresh water intake. In order to leach gold and silver in the presence of high levels of copper and nickel, excessive amounts of cyanide must be added until this becomes a limiting factor in the profitability of the operation, especially if cyanides must be removed from the effluents. The degree to which solutions can be recycled is, of course, determined by the amount of base metals in solution.

If, however, a successful and economically attractive method of recovering base metals and regenerating cyanide from such solutions could be developed, the solutions would be recyclable indefinitely. Such a process seems now to be potentially available:

Mahad Adh Dhahab Gold Mine

The Mahad Adh Dhahab Gold Mine and Mill that is being established in Saudi Arabia is an example of a mine that will be located in a desert a long way away from a water supply. Water will be pumped to the site by pipeline across the desert. In this case, even though CIP has been selected because of its improved metallurgical recovery, the tailings will be filtered before they reach the tailings pond as a way of recovering more water for reuse, thereby avoiding some of the evaporation losses that would occur if the normal system of decanting tailings were to be applied in the intense heat of the Arabian Desert. More information on this flow sheet and its estimated water needs can be requested from:

Western Mining Corp., Kambalda, WA

The Kambalda ore contains cyanide-soluble copper and nickel which would interfere with zinc precipitation but is at manageable levels for CIP. To reduce the interference of copper and nickel loadings on carbon at Kambalda, free cyanide levels are kept high in the pulp solution. Despite the very high cost of water used for this operation at A$1.00/m^3 or A$1 million per year, only 36% of the water can be reclaimed from the tailings pond for this reason.

CARBON ADSORPTION VS. MERRILL-CROWE AND WATER RECYCLING

The opportunity to recycle cyanide solution is very much different for CIP and zinc precipitation circuits. For one thing, to optimize gold adsorption on carbon from clean pulps, it is best to get free cyanide concentration as low as possible. This can be done by modifying the pH, air agitation and avoiding the use of excess cyanide in the first place. Also, there is no solid-liquid separation step ahead of the tailings pond, so the only opportunity to recycle solutions is by decanting the tailings in the pond. Residence in the tailings pond (especially in warm climates) will destroy much of the cyanide left in this solution.

On the other hand, when zinc precipitation is used, cyanide solution is separated from the ore solids and after gold recovery, can be recycled to the leach end of the process

without further cyanide losses. Of course, the zinc added builds up in solution as a zinc cyanide complex until a barren bleed is necessary.

In general, the conventional gold precipitation circuit arrangement offers the advantage of being able to use a little less water and of being able to reduce cyanide consumption compared with CIP.

Gold and Uranium Operations, Witwatersrand

In the current arrangement on the Witwatersrand, many of the mines and mills are zero discharge operations. Although no solutions are discharged as surface effluents, except surface runoff perhaps and sewage plant effluents, it is likely that solution is lost due to seepage from tailings and reclaim solution reservoirs in some cases. The chance of seepage losses from the older sand tailings is greater than from the more modern slimes dams, especially those using the "semi-dry" or "sub-aerial" disposal method and also depending on the permeability of the soil beneath the tailings impoundment.

If these seepages have to be prevented at some time in the future, then the water and salt balances will change accordingly.

Most gold mills on the Witwatersrand are associated with metallurgical plants which recover uranium by acid leaching. An interesting phenomenon is found in South Africa. When recycled water is used for washing the gold rotary filters, there is less blinding of the filter media than when Rand Water Board water is used.

Vaal Reefs Exploration and Mining Co. Ltd.

The Vaal Reefs mining and metallurgical complex treats nine million tons of ore annually in a series of gold and uranium recovery operations. Tailings are mined with uranium plant raffinate and 10 Kg lime/ton tailings and aerated prior to the tailings being pumped to the tailings dams. Water decanted from these dams is recycled to each of the metallurgical operations for reuse. This form of macro recycle is effective in that overall new water requirement for both gold and acid uranium leaching amounts to 0.9 m^3/ton ore, and the operation achieves zero discharge. Additional water, however, is added to the system in the form of treated sewage effluents from five sewage plants which represents a sizeable volume of water. The operations are located within a loop of the Vaal River, and monitored water analyses of the river water indicate that seepage and surface runoff from this mammoth operation is under control.

Rand Mines Milling and Mining Co. (Pty) Ltd. (RM3)

At RM3, secondary water sources are relied upon entirely in the recovery of gold and pyrite by flotation and CIP of the leached flotation tailings. Water is recycled to the

greatest possible extent as shown in a diagram in the trip report on RM3 in Appendix I. It is believed that gold recovery has not quite matched pilot test results due to water quality problems. First, one of the surface water sources upstream of the RM3 uptake is impacted by industrial effluents which seem to add organic constituents and oxygen consumers to the water. Second, the water in closed loop contact with the tailings undoubtably builds up levels of ferrous ions and partially oxidized sulfur and organic compounds which may impact both leaching and carbon adsorption of gold.

East Rand Gold and Uranium Company Ltd.

At ERGO, 1.6 million tons per month of tailings are reclaimed by repulping them using monitor hoses. Minewater from nearby deep underground mines is used together with tailings recycle water. After flotation of pyrite and gold at an acid pH, the tailings are neutralized and treated by CIP to recover gold. The last 7 stages of the 11-stage CIL train serve to remove cyanide from the pulp prior to tailings being pumped to a new tailings dam. Water from this dam is decanted and returned to the plant. The operation is described in Appendix I. Despite the degree of water recycling and high TDS, scale is not a serious problem in the tailings return solution lines, but it is in the monitor water lines, and special scale inhibiting measures are employed. Wherever cyanide is used to leach tailings or calcine for gold recovery, it is treated before being discarded to tailings to avoid cyanide returning to the flotation plant (where it would inhibit pyrite recovery) or becoming a pollutant.

GOLD AND SILVER RECOVERY, U.S.A.

Most gold and primary silver recovery operations are located in the drier western states of the U.S.A. where zero discharge is possible from a climatic point of view. At most of these oparations, water is recycled without serious effects. Two operations in the west where zero discharge is not achievable are the NORANDA Grey Eagle Mines in northern California and HECLA Mining's Knob Hill Mine at Republic, Washington, where precipitation exceeds evaporation. In the case of NORANDA Grey Eagle Mines, excess solution from the CIP tailings dam is treated by alkaline chlorination before it can be disposed of by spray irrigation to a field. At Knob Hill, the excess solutions are sprayed into the air to enhance evaporation. In both operations, tailings decant solution is also recovered for recycling to the mill.

At the Battle Mountain operation of DUVAL CORP. which uses CIP, recycling of solution is not possible as there are no topographic possibilities for a tailings pond at the same level as the mine and mill, both of which are located on top of a hill (mountain) while the tailings are disposed of in the valley floor below. Also, cyanide-soluble copper levels in the ore result in copper levels in solution close to the limit at which metallurgical problems would occur if the water was recycled without treatment. The Battle Mountain plant was converted to gold leach and recovery from a copper flotation operation. Had it

not been for the fact that abundant fresh water was available from a well near the minesite, their water management arrangements have had to make provision for water recycling as well.

Getty Mercur Mine, Tooele, Utah

The Getty Mercur Mine at Tooele, Utah, is interesting from a water recycling point of view. This is one of the few operations that recycles tailings decant solution back to the operation but where cyanide in the recycled solution is destroyed deliberately before reuse of the water.

The reason is that the Mercur ore is preg-robbing and, if cyanide were to get into the grinding circuit, gold would start leaching and would be adsorbed on the pregrobbing species in the ore. The aim at Mercur is for the ore to start leaching in cyanide only after it is brought in contact with activated carbon in a true carbon-in-leach arrangement.

Recycled solutions are treated with hypochlorite before being returned to the mill.

Rustenburg refiners, Rustenburg

Maximum use is made of recycled water at the Rustenburg Refinery which recovers a platinum group metal concentrate and copper, nickel, and cobalt salts from a roasted matte.

The water management program allowing the high degree of recycling is sophisticated and incorporates evaporation of the final metallurgical solutions to recover sodium sulfate crystals and water as well as reverse osmosis for the treatment of utility wastewater as a means of achieving zero discharge. The evaporators yield a salable sodium sulfate product. A lime-soda softening process is employed to treat reclaimed process water before it is returned to the process.

In this case, recycling of process water is so efficient that if chloride in incoming water is higher than usual, it builds up in the process solutions until eventually presenting a corrosion problem in the stainless steel autoclaves employed.

Efficient water recycling leads to efficient salt load accumulation which eventually must be bled in one or another way to maintain a balance.

Rustenburg Refiners' water management program is briefly discussed in Appendix I.

In the Rustenburg Platinum Complex, a tailings impoundment is used in which, because of efficient recycling, TDS levels are building up. The sulfate solutions have been

neutralized with lime and are close to saturation with $CaSO_4$. Underdrains for controlled release of water from tailings are an advanced design feature, but the metallurgical industry has not yet completely worked out how to avoid underdrain clogging due to scale formation, or under what conditions it will occur and what to do about it if it does.

ECONOMICS OF WATER RECYCLING

The economics of water recycling in mine-mill environments varies from site to site and cannot realistically be discussed here in quantitative terms. The extent of recycling should be increased in increments until the benefits no longer outweigh the costs. This is a tradeoff of the following factors.

Benefits of Recycling

1) Price of water saved.

2) Price of reagent savings, e.g., pH adjustment, cyanide, etc.

3) Cost of alternative water treatment or evaporation saved by recycling instead of discarding.

4) Value of incremental recoverable resource that would be lost were it not for recycling of solution after adjustment for the concentration enhancement due to recycling.

Cost of Recycling

1) Cost of reclaiming and pumping.

2) Extra cost of solution storage.

3) Incremental cost of scale or corrosion caused by recycling.

4) Cost of incremental impact on metallurgical efficiency recycling.

5) Cost of catering to problems such as the cementing up of multi-media polishing filters.

Of course, the economics of recycling are clearcut if an operating permit or water supply constraints are such that the operator has no option but to recycle as much water as possible in order to stay in business.

PROBLEMS ARISING FROM WATER RECYCLING

The problems that arise from water recycling were reasonable well documented in the above examples. These may be summarized as follows:

1) Buildup of TDS and contaminants.

2) Enhanced corrosiveness or scaling characteristics of recycled water.

3) Possible introduction to the front of the process of reagents that interfere with the front end processes, e.g., hexavalent chromium to Cu-Pb-Zn flotation or CN^- to mill treating a pregrobbing gold ore.

4) TDS increase in solutions as they are recycled, eventually resulting in problems such as in pregnant solution polishing ahead of metal recovery, e.g., SX for uranium or zinc precipitation for gold and silver. Fortunately, there are innovative new ways to polish solutions.

5) If metallurgical operations are operated for true zero discharge (in climates with a net evaporation), through efficient water recycling, then the salt load will also build up in tailings and process solutions. The concentrations of species such as $CaSO_4$ may exceed saturation, and there is a possibility of underdrains of tailings impoundments becoming scaled up. This is potential problem that is being studied by industry in the hope of finding answers before the problem occurs.

6) If water and salts contained in solutions are recycled, at some point there must be a salt bleed. Evaporation ponds are one way in areas where there is adequate space. In the future, increasing use will have to made of more sophisticated water recovery processes such as multi-effect evaporators, etc., as are used routinely in the chemical industry.

CHAPTER 6

SUMMARY OF WATER QUALITY STANDARDS

The mining and mineral processing industry is impacted by several levels of water quality standards. These vary from country to country, state to state, county to county, and even site to site. In the U.S.A., the following seem to apply:

Federal Water Quality Standards
State Water Quality Standards
NPDES Permits for Effluent Discharges
Federal Drinking Water Standards
Federal Water Quality Objectives

A similar multi-level system of standards has also evolved in Canada where federal, provincial levels, and permit levels apply to a given project.

In South Africa, there are two and soon will be three National Standards relating to surface effluent discharge from industrial operations including mining. These are the so called general standard applicable everywhere, the special standard for the special protection of several disignated stretches of river which are said to be capable of supporting trout fisheries, and the new PWVS standard for operations in the Pretoria-Witwatersrand-Vereeniging-Sasolburg region where buildup of TDS in the Vaal Dam has necessitated more careful protection of surface water discharges.

In the United States, perhaps the most stifling of all is the pending regulation of solid waste disposal by mines and mills at the federal and state level since it is not yet established what these rules and criteria will be. Although the Beville Amendment rules that the federal RCRA laws governing hazardous waste do not apply, temporarily, to mining and mineral processing wastes, congress is busy working on a new set of rules designed to apply to the disposal of mining and mineral processing waste to prevent damage to surface and groundwater resources. Certain states, including the trend-setting state of California have established hazardous waste disposal laws that are even stricter than the RCRA rules, and in California the rules are applied to mining and mineral processing wastes. These rules are less of a water standard than a set of criteria by which to judge whether a particular waste is or is not to be classified as a "hazardous" waste. This is determined primarily by a short-term leach test using a weak acid (citric acid in California, acetic acid at pH 5 for the federal EP toxicity test). If judged to be hazardous by these criteria, then a special set of waste disposal regulations for "hazardous" waste disposal must be followed.

Apart from the questionable applicability of short-term acetic acid or citric acid leach tests as a realistic means of determining whether waste is hazardous or not, a major problem arises in that the list of elements and their criteria levels in the leachate has not been finally decided. The EPA reputedly is extending their list significantly. "hazardous waste" disposal rules are in varying stages of evolution state to state and for the next several years, these promise to continue to be a moving target. If one is contemplating a new mining and mineral processing operation in several parts of the U.S.A. at this time, it is not crisply defined what water quality standards will apply for effluents that have to be discharged nor what will be required in the way of groundwater protection for wasterock and tailings disposal.

Before discussing water quality standards themselves, it is important to recognize that in the U.S.A., the general rule is that there shall be no discharge of effluents at all from metallurgical and mineral processing operations except where precipitation exceeds evaporation in which case, effluents must be treated to meet the levels set out in the NPDES permit. In other words, all mineral processing and ore treatment operations must be zero discharge except where climatic constraints make this impossible. Minewater is subject to NPDES permitting and must be treated to meet permit requirements.

The way this works in practice is that water released from say a uranium mine in New Mexico may be released after treatment to meet NPDES permit requirements. Effluent from the mill or tailings pond decant may not be released because in New Mexico evaporation exceeds precipitation, and "zero discharge" can be achieved. In this case, mill process and tailings effluents must be impounded and evaporated.

At the Homestake Mining Company's McLaughlin project which is in a climate where, on average, evaporation exceeds precipitation, again no mill or tailings effluents may be discharged. A comprehensive NPDES effluent discharge permit is nonetheless required with extensive sampling and monitoring requirements for runoff that may occur from the affected area which covers several square miles. This NPDES permit is included in the McLaughlin trip report in Appendix I.

DISTINCTION BETWEEN EFFLUENT PERMITS AND OBJECTIVES

An important distinction neds to be made between the levels shown for contaminants in NPDES permits and various water quality objectives for environment protection. NPdES permit levels apply to concentrations of contaminants in the effluent itself. Water quality objectives and drinking water standards apply to the level of a contaminant in the receiving waters or drinking water itself. Another distinction between effluent limit permits and objectives is that the first describes a legal requirement while the second describes what the state would like to achieve if possible.

CERCLA - SUPERTHREAT

One aspect of the permitting and regulatory process in the U.S.A. should be of particular concern to mining companies operating in the U.S.A. CERCLA or Superfund rules are such that even if an operator fulfills all the requirements of their NPDES permits during the life of the operation, if years later after the operation has been shut down, the site is found to cause contamination of an aquifer or stream, lake, etc., then under CERCLA (Superfund) rules, the original owners of the operation can be persued by the state to pay for whatever measures are deemed necessary to stabilize the site and repair whatever damage has been done. Under CERCLA rules, the original operator may be sued for up to $50 million for "each occurrence" of contaminant release from the site. The meaning of "each occurrence" is believed about to be tested soon in court in Colorado.

What this seems to mean is that if an operation is successful at negotiating lenient permit requirements from regulators when he goes into production or if the measures required by the state at the time prove to be inadequate or inappropriate in the long run and damage results to the environment years later, then the state and private organizations representing "the people" may sue the owners of the operation for tens and even hundreds of millions of dollars in reparations.

One other point must be made before listing water quality standard and permit data. The data listed below refers to mining and mineral processing effluents. It does not apply to smelters, refineries, or metal finishing operations.

BASE METAL REFINERIES AND SMELTER EFFLUENT RULES - U.S.A.

For base metal refineries, the rules are now very much more complicated. The EPA has devised a series of technolog-based standards specifying not only the concentration of contaminants that can be released from smelters and refineries, but also the total amount of each contaminant that can be released daily in the total effluent from such plants including runoff. The regulations in the U.S.A. seem also to specify what type of treatment process shall be used. For a given type of works, the EPA has attempted to establish a "building block" framework for calculation of permissible amounts of contaminant release permitted daily. Each processing step in the plant is allowed to contribute a certain number of pounds per day of contaminant to the final effluent, and these allocations for the whole plant are then added to compute the maximum total amount of each contaminant in the final effluent. To bad if a new process step is used which is not included in the regulated list as for that part of the process, no contribution to the final effluent is allocated. Also, the allowable contaminant allocations for each step in the process are based on a production level at the plant. Presumably, if operations are suspended for a period of time, then the allowable effluent contamination drops to zero

for that period. The nature of the regulations governing discharges from smelters and refineries is so complicated that it is not practical to try to include them in the list of water quality standards tabulated below. Sponsors are referred to the Federal Register, Thursday, March 8, 1984, 40 CFR, Part 421, Part II, Environmental Protection Agency, titled "Nonferrous Metals Manufacturing Point Source Category; Effluent Limitation Guidelines, Pretreatment Statdards, and New Source Performance Standards; Final Rule," pp8741-8831. Although aspects of these effluent level determining procedures are subject to a suit filed by the American Mining Congress against the U.S. EPA, the final regulation document illustrates the complexity and unwieldiness of the present system for non-ferrous smelters and refineries in the U.S.A.

BRAZIL

Effluent limits for industry, which include mine-mill operations in Brazil, are specified in site specific permits. The following general maximum guidelines are used in three industrialized provinces of Brazil:

Parameter	Unit	Rio	S. Paulo	Minas Gerais
pH	-	5-9	5-9	6-9
Sedim. Solids	ML/L	1.0	1.0	1.0
DB05	MG/L	(*)	60	60
Cyanide	MG/L	0.2	0.2	0.2
Arsenic	MG/L	0.1	0.2	0.2
Copper	MG/L	0.5	1.0	0.5
Lead	MG/L	0.5	0.5	0.1
Zinc	MG/L	1.0	5.0	1.0
Nickel	MG/L	1.0	2.0	1.0
Mercury	MG/L	0.01	0.01	0.01
Cadmium	MG/L	0.1	0.2	0.1
Chromium III	MG/L	1.0	5.0	1.0
Chromium VI	MG/L	1.5	0.1	ND
Fluorides	MG/L	10	10	10
Sulfides	MG/L	1.0	-	0.5
Oil and Grease	MG/L	20	100	20
Temperature Degc.		40	40	40

* Biological oxygen demand (5-day) depends on the receiving water quality (flowrate, flow pattern, and dissolved oxygen level).

Note: Priority pollutants such as carcinogens are submitted to specific legislation.

The above limits must not be exceeded for mine drainage, rain water runoff, and process effluents.

RANDOL is indebted to Natron, a leading firm of environmental engineers and consultants, for the above information.

SWEDEN

No fixed limits of contaminants are specified in mine-mill discharges. These are set on a site specific basis through negotiation with licensing authorities. These are the Franchise Board in Stockholm and the Water Court of which there are several scattered across the country.

Examples of effluent limits which have been agreed upon include the following examples provided by BOLIDEN A/B:

pH	Case 1: pH 7 Case 2: pH 8
Suspended Solids	Max. 10 mg/l
Combined Cu, Pb, Zn, Cd, As, Hg	1 mg/l (Monthly Average)
Cr	0.1 mg/l
CN (Free)	0.5 mg/l (Monthly Average) 0.2 mg/l (From July, 1986)

INTRODUCTION

The U.S.A. initiated the wave of environmental awareness and the rapid growth of bureaucratic organizations to protect the environment. Mining and mineral processing is not the prime target of these bureaucracies who have had to deal with a wide range of industries, all at the same time, even though at times it feels to the industry as though they are. Regulation of mine and mill effluents as an environment protection measure has spread rapidly to other parts of the world, and there is virtually nowhere that a new mine could be started today without having to meet strict effluent discharge control regulations.

The huge Ok Tedi gold recovery operation in Papua New Guinea, had to meet effluent limits with respect to cyanide comparable with those in North America. U.S. environmental consultants were hired to advise both the Papua New Guinea, government and the owners of the project. When the Anglo American Corp. planned the recovery of gold from a new arsenopyrite gold deposit near Morro Velho, Brazil, the limits for arsenic that had to be met in their effluent (0.2 mg/l) were comparable with those in the U.S.A., although they were able to install a roaster which would be a questionable endeavor in North America at this time. This may have something to do with the shortage of sulfuric acid in Brazil.

South Africa is revising its regulations with respect to the protection of surface and groundwater quality, and the final ramifications of these regulations are not yet known. What is known is that they will be stricter than before, although the emphasis on the Witwatersrand will be more on preventing TDS buildup in the Vaal Dam which is the regional water supply to the industrial heartland of the country.

Most of Europe with its high population density has a well-developed environment protection regulatory system. Trout live successfully in a stream that receives effluents from the only gold cyanidation plant in France.

Australia is also very concerned with environmental aspects of mining and mineral processing. The Deep Leads, a gold resource in the state of Victoria which is suitable for in situ leaching, has not been exploited for lack of a permit to impact the aquifer in an agricultural region. In Kalgoorlie, Western Australia, there is some question as to whether another roasting plant would be permitted in the Golden Mile area. Regulatory requirements for environmental protection at uranium mines in the Alligator Ridge area of the Northern Territory have been as stiff or stiffer than those in the U.S.A.

In New Zealand, the public mostly appears to be against mining of any sort. Opponents to a mining operation which proposed to excavate only 50,000 tons used old photographs of Bingham Canyon to illustrate their cause. New Zealand is not a "mining country," and permits to open a metals mine there would be very difficult to obtain.

REFERENCES 261

Some Considerations on Environmental Regulations Relevent to Hydrometallurgical Process Residue by SUN K. KIM and ROGER N. KUSH, AIME, Dallas, Texas, February 14-22, 1982 263

Canada is one of the major mining countries of the world along with South Africa and the U.S.A. Canada and South Africa are more alike in that both recognize the importance of the mining industry to their economies, while both also recognize the need for improved environmental protection. Environmental protection in both cases means protecting the quality of water. In fact, in Canada, the environment protection laws and effluent discharge permits are administered under the Fisheries Act.

Although alike in that both countries are concerned about the quality of mining and mill processing effluents, they are quite different in their motivation for water quality protection. Canada accommodates 37% of the world's fresh water resource while South Africa is a dry country with just a few oases. In Canada, rules are made primarily to protect valuable inland fisheries. In South Africa, the new modifications to effluent discharge regulations are aimed at protecting the quality of their limited water resources which have been recognized as a factor that will limit the future growth of their economy.

In the main mining countries of the world, motivation for environmental protection is reflected in the nature of the mine and mill effluent regulations, i.e., protection of fisheries in Canada, and protecting water quality in the Vaal Dam in South Africa. The U.S.A., however, although it is the leader in all aspects of understanding the environment, analyzing and monitoring techniques, and in the availability of equipment and technology to treat water and effluents, is possibly the furthest behind in developing a workable set of regulations for environmental control, i.e, preservation of surface and groundwater quality. Both Canada and South Africa recognize the need to keep their mining industries alive even if there is an environmental price to pay--within limits. The emphasis in these two countries is by and large placed on doing what can be done without destroying the industry or costing too many jobs.

U.S.A.

In the U.S.A., the two main areas of near term concern are the amended Resource Conservation and Recovery Act, RCRA, rules expected to govern "hazardous waste" disposal as applicable to solid waste from mines and mills, i.e., wasterock and mill tailings, and the CERCLA-Superfund Law implementation. RCRA rules may well also be applicable when metal precipitates or desalination concentrates are generated in effluent treatment processes, and it is conceivable that effluent treatment requirements may result in the generation of "hazardous" wastes requiring special disposal conditions. The EP toxicity test which is a criteria used to determine whether non-mining wastes are "hazardous" was described in EPA (1978). Toxicity is exhibited if any of the contaminants listed by the EPA exceed the limits established by the EPA (1980) and also listed by KIM and KUST (1982) at the end of this chapter which are 100 times the primary drinking water standards (PDWS). It is now rumored that the EPA is about to greatly expand the list of elements included in the EP toxicity test and to make the limits

for the existing list of elements more stringent, but this has yet to be officially confirmed. There is such a potential "bite" to some of these regulations that they have already become a factor in scaring away potential foreign investment in U.S. minerals exploration and mining industry.

A major problem with BAT (Best Available Technology) regulations for metallurgical process effluents is that often as new treatment processes are demonstrated in laboratories by professors, the EPA latches onto them and sets a new limit--stricter than the last--based on the capabilities of the new technology demonstrated under ideal conditions rather than in real life mine environments. In effect, the regulations present a moving target.

One of the most difficult set of environmental protection regulations or pending rules for the U.S. mining industry to contend with is CERCLA--the Superfund regulations. The reason is that no matter whether or not an operation complied with all effluent and solid waste requirements at the time their tailings and wasterock were disposed of, if at some future point it is discovered that they are causing damage to the environment, the original owners of the operation can be sued years later for reparations to force them to pay for the repair of the damage and stabilization of the site. CERCLA suits run up to $50 million per occurrence and, with several possible contaminant release occurrences from the same property, Superfund suits run into hundreds of millions of dollars. The U.S. law also makes provision for citizen-suits against mining companies that cause environmental damage, or which fail to meet their permit requirements. Private groups in the U.S.A. also have the legal right to demand company files and reports lodged with regulators and, if they find incidences where permit requirements have not been met, they may force litigation against that company.

Most federal regulations are formulated in Washington where the mining industry is represented by lawyers working for the AMC (American Mining Congress). Regretably, there are indications that Washington is far removed from the practical problems and site-specific nature of the mining and mineral processing industry in the western states. The EPA headquarters in Washington seems bent on formulating a uniform set of regulations applicable to every mine in the country. Washington does not appear to want to listen even to their own people in the regional offices who have the field experience and know the site-specific nature of mining and mineral processing waste and of its impact on different types of environments in different topographies and climates. The industry awaits the pending new federal rules governing solid waste disposal by mines and mills with some apprehension.

Unlike any other country, in the U.S.A. new regulations are scrutinized also by publicly-funded organizations such as the Natural Resources Defense Council Inc., and others who take legal action which, in the recent past, has forced the issue successfuly, setting time limits for new regulations and contesting whether or not proposed regulations

are strict enough. Most of their actions are based on "eastern thinking" which seems to believe that all environmental impacts of mining can be solved overnight through technologies selected in Washington by lawyers. The result in the U.S.A. has been that regulators have tended to over regulate the mining industry while at least some of the mining industry has argued for no regulation with the result that a confrontational atmosphere has prevailed. This, in turn, has served neither the environment nor the mining industry constructively.

The public hearing process that goes into the granting of permits for mines and mills in the U.S.A. has also encouraged the evolution of vociferous anti-industry private groups that seem to oppose all industry on principle. These protestors pop up to oppose nuclear power, mining projects, automobile plants, and housing development. Very often, mining companies end up agreeing to do things to appease these anti-industry groups rather than because the agreed upon actions are reasonable or meaningful. These groups also influence public servants charged with regulating the mining industry.

Another significant trend in regulations that affects the U.S. mining industry is the shift in roles of Washington (i.e., the federal government) and state-level government. Although federal rulemakers continue to make new rules, the implementation of these rules is being shifted to the individual states. The way this is done is for jurisdiction to be transferred to state regulators once that state has enacted and can show it has the ability to enforce rules at least as stringent as the federal rules. This has two results. First, several states have enacted much stricter regulations than the federal rules; second, in those states that have limited experience with mining, it now takes "forever" to secure a permit while local regulators learn about the special needs and character of mining. A case in point is EXXON's Crandon project in Wisconsin which has been seeking a permit for a mine and mill for at least four years. In some counties of California, local ordinances have been passed recently which will make mining in those counties virtually impossible.

Fortunately for the industry, there are still states, such as Nevada, that welcome mining. However, for a mining company with nationwide interests, keeping up with and helping in the formulation of regulations concerning environmental protection (which means water) in all fifty states, has become a virtually impossible task. Much focus has been placed lately on the California Mining Association which strives to help mold some reason and perspective in regulations being formulated by that state, which is considered a trend-setting state. Although much progress has been made in tempering the California regulator's attitute toward mining, if California is trend-setting with respect to hazardous waste disposal by mines and mills, then the industry has much to be concerned about as other states model themselves on California. In the U.S.A., most states are electing to be "agreements states," that is, they agree to impose and regulate environmental (including water resources) rules at least as stringent as the federal regulations laid down by congress as proposed by the EPA.

The role of the U.S. EPA, it appears, is becoming more that of federal rule formulator to set the minimum standard and an advisor to the individual states when called upon. If a state fails to regulate the mining industry in accordance with its agreement, then the EPA, through its regional offices, will step in to do so.

In becoming an "agreement state," a state becomes eligible for federal funds for application in enforcing its regulations.

Another important trend in the U.S.A. is the new EPA focus on groundwater quality protection. This has a significant impact on solid waste disposal from all industries that could have an impact on groundwater through direct seepage or runoff followed by seepage from solid waste disposal sites. Consequently, it is clear that for the immediate future, significant attention will be focussed on mine waterock, mill tailings, evaporation ponds, and water/solution impoundments. This attention will be reflected in new regulations within the next one to two years. Some insight into this was obtained in a draft of EPA (1984) strategy.

In the U.S.A., generally, rainfall exceeds evaporation in the eastern half of the country and vice versa in the western states, except the very far northwest and Alaska.

A common denominator in U.S. regulations governing effluents is that there shall be no discharge of effluents from mineral processing where this is possible within climatic constraints. The impact of surface water related regulations was that much greater where effluent discharge could not be avoided, i.e., the east. The impact of anticipated groundwater-related regulations will be pretty much the same for all parts of the country.

The uranium mining and milling industry in the U.S.A. is regulated entirely by the Nuclear Regulatory Commission. Once again, however, individual state environment protection departments have the option to regulate this industry within their own states, provided their regulations and implementation thereof are at least as stringent as the NRC regulations. One of the most significant guidelines in uranium milling is a document known as the Generic Environment Impact Statement by uranium milling and waste disposal.

Uranium waste materials were specifically excluded from the RCRA rules governing hazardous waste disposal, but uranium mines and mills are not excluded from CERCLA (Superfund) regulations and, in fact, several uranium mill tailings and former mill sites have been listed as Superfund sites.

CRITICAL REGULATIONS - U.S.A.

KIM and KUST (1982) reviewed environmental regulations relevent to hydrometallurgical process residues.

At the American Mining Congress meeting in San Francisco, September, 1983, a session reviewed The Environment: Legislative and Regulatory Update, and Government Controls and the Environment: Superfund-Superproblem. This set of reports provides a good review of the critical regulations emerging in the U.S.A.

In addition, sponsors are referred to EPA (1982) on Ore Mining and Dressing, Point Source Category Effluent Limitations Guidelines, and New Source Performance Standards, and also a very confusing document, EPA (1984), on 40 CFR Part 421: Nonferrous Metals Manufacturing Point Source Category; Effluent Limitations, Guidelines, Pretreatment Standards, and New Source Performance Standards; Final Rule. The Preamble of this document is inserted below as it provides additional insight into the background of some of the important legislation that has recently been passed by congress.

PEDCo (1983) completed their report to the EPA on their analysis of solid waste (wasterock, mill tailings, precipitate sludges) and water that had been in contact with solid wastes. Based on the PEDCo (1983) report, congress will decide upon a new set of regulations designed to protect groundwater from solid waste generated by mining and mineral processing industries that EPA, Washington, is currently drafting, apparently with minimal help from EPA regional offices which are the ones that have direct field experience with industry.

As far as state regulations are concerned, California is leading the way with their set of regulations governing solid waste disposal.

A copy of a recent NPDES permit issued by the state of California to the Homestake Mining Company for their McLaughlin project is inserted below as an illustration of the types of requirements of such permits. It is to be borne in mind that this mine and metallurgical processing facility will be zero discharge, and the permit applies only to runoff surface runoff water not contained by the extensive collection system installed to prevent runoff from leaving the property.

The first Superfund lawsuits relating to mining and mineral processing suits are currently being served and in due curse, the outcome of these will determine to what extent CERCLA laws have a bite to them. Companies believed to be involved in Superfund sites are:

Anaconda Company	East Helena, Montana
ARGO Tunnel	Idaho Springs, Colorado
Asarco	Globe Smelter, Denver
Asarco	Leadville, Colorado
Cotter Corp.	Canon City, Colorado
Gulf & Western	Gilman Mine, Gilman, Colorado
Gulf & Western	Palmerton, Pennsylvania

Newmont Mining Co.	Idarado Mine and Mill, Telluride, Colorado
Union Carbide Corp./Umetco	Uranium Mill, Colorado
Vitro Uranium Tailings	Salt Lake City, Utah

There are many more Superfund sites, but the above sampling indicates the diversity of companies and industries involved.

Flotation mill tailings from selective flotation operations containing cyanide were originally listed in Appendix VII to Part 261 of IOCFR regulations as hazardous wastes from non-specific sources and given the "generic" waste number F013. During the commentary period, EPA agreed to delete this item from the regulation based on a comprehensive document prepared for AMAX Environment Services, Inc. by:

ENGINEERING SCIENCE, INC.
2785 North Speer Blvd.
Denver, CO 80211
(303) 455-4427
Allen L. Udin

"Pertinent Information Regarding Complexed Cyanides in Mineral Flotation Tailings," July 1980.

The hazardous waste regulations (RCRA) have been challenged in court by the mining companies, the American Mining Congress, and individually by companies such as AMAX, Inc., who object to the acetic acid EP leach criteria. This litigation was still in progress when RANDOL heard about it.

SOLID WASTE PROGRAM

For "non-hazadous" waste, congress encouraged the creation of effective solid waste management plans at the state level. The EPA was to promulgate guidelines for the development and implementation of state solid waste management plans. The controversial aspect of the program is included in Section 4005 of the Solid Waste Disposal Act, which provides that any solid waste management practice constituting "open dumping" is prohibited. To avoid constituting "open dumping," the disposal site would have to qualify as a "sanitary landfill" as defined by EPA promulgated criteria as found in 40CFR, Part 257. This subject is discussed in greater detail by MARUCHEAU (1983).

U.S. ACTS OF CONGRESS - FEDERAL LAW

CLEAN WATER ACT of 27 December, 1977) Sections 301, 304, 306, 307, 308, and 501 (The Federal Water Pollution Control Act, Amendments of 1972, 33, USC 1251, et sequ. as amended by the Clean Water Act of 1977, P.L. 95-217).

Sections 301(b)(2)A and 301(b)(2)C:

Require achievement by 1 July 1984 of the effluent limitations requiring application of BAT for toxic pollutants including the 65 priority pollutants declared toxic by Congress under Section 307(a) of the Federal Water Pollution Control Act of 1977.

Section 304(e):

Authorizes the Administrator of the EPA to prescribe "best management practices (BMP's) to control release of toxic and hazardous pollutants from plant site runoff; and spillages or leaks; sludge or waste disposal; and drainage from raw material storage associated with waste disposal; and drainage from raw material storage associated with or ancillary to the manufacturing or treatment process.

Section 301(b)(2)(E):

Establishes best conventional Pollutant Control Technology (BCT) for discharges of conventional pollutants from existing industrial point sources. Conventional pollutants are those defined in Section 304(a)(4) [biological oxygen demanding pollutants, total suspended solids, fecal coliform and pH as well as any other additional pollutants defined by the Administrator as conventional, e.g., oil and grease.].

Solid Waste Disposal Act, SWDA, of 1965, Section 4005:

"Open Dumping" of solid waste, i.e., other than in a sanitary landfill is prohibited.

The Clean Water Act of 27 December, 1977, Sections 301, 304, 306, 307, 308, and 501 (The Federal Water Pollution Control Act Amendments of 1972, 33, USC1251, et sequ. as amended by the Clean Water Act of 1977 P.L. 95-217).

Settlement Agreement in 'Natural Resources Defense Council, Inc. V. Train. 8ERC 2120 (DDC 1976) modified, 12ERC 1833 (DDC 1979). Requires EPA to promulgate BAT effluent limitation guidelines by a fixed date and NSPS covering 65 classes of toxic pollutants subsequently defined by EPA as 129 specific "priority pollutants."

Pollution Control Act Amendments of 1972, Section 301(b)(1)(A):

"By 1 July 1977 existing industrial dischargers were required to achieve "Effluent limitations requiring the application of the best practicable control technology currently available (BPT).

Federal Water Pollution Control Act Amendment of 1972, Section 301(b)(2)(A):

By 1 July, 1984, these dischargers were required to achieve "Effluent limitations requiring the application of best available technology economically achievable...which will result in reasonable further progress toward the national goal of eliminating the discharge of all pollutants (BAT). These included 65 priority pollutants declared toxic by Congress under Section 307(a) of the Federal Water Pollution Control Act of 1977. Federal Water

Pollution Control Act Amendments of 1972, Section 306: New Source Performance Standards (NSPS) based on best available demonstrated technology (BADT).

RCRA:

Resource Conservation and Recovery Act of October 21, 1976, Section 8002(f) and Solid Waste Disposal Act Amendment of 1980, Section p: Mandate for the Study of the Impact of Solid Waste from the Mining Industry--Led to the PEDCo Study.

CERCLA:

Comprehensive Environment Response, Compensation, and Liability Act, 1980.

The Beville Amendment to RCRA:

Solid Waste Disposal Act of 1976 as amended 1980 under RCRA Deferred Regulation of Certain Wastes as "Hazardous" Wastes until at least 6 months after the submission to Congress by EPA of reports relating the results of studies on the exempted wastes. The exempted wastes include "solid wastes from the extraction, benefication, and processing ores and minerals, including phosphate rock and overburden from the mining of uranium ore." This refers to the PEDCo study mentioned above.

Federal Water Pollution Control Act Amendments of 1972, Section 402:

The requirements for direct dischargers of industrial effluents were to be incorporated into the National Pollution Discharge Elimination System (NPDES) permits issued under Section 402 of the Act.

Federal Water Pollution Control Act Amendments of 1972, Section 402(a)(1):

Authorizes the setting of requirements for direct dischargers on a case-by-case basis. Note: EPA claims that congress intended that control requirements would, for the most part, be based on regulations promulgated by the Administrator of the EPA.

Federal Water Pollution Control Act Amendment of 1972, Section 304(b):

Requires the Administrator of the EPA to promulgate regulations for effluent limitations setting forth the degree of effluent reduction attainable through the application of BPT and BAT.

Federal Water Pollution Control Act Amendment of 1972, Section 304(c) and 306:

Requires promulgation of regulations for NSPS (New Sources of Pollution).

Federal Water Pollution Control Act Amendment of 1972, Section 307(a):

Requires the EPA Administrator to promulgate effluent standards applicable to all dischargers of toxic pollutants.

Federal Water Pollution Control Act Amendment of 1972, Section 501(1):
Authorizes the EPA Administrator to prescribe any additional regulations "necessary to carry out his functions under the Act."

Clean Water Act of 1977, Section 304(b)(4)B:
Requires BCT limitations be assessed in light of a two-part "Cost Reasonableness Test." The first test compares the cost for private industry to reduce its conventional pollutants with the costs to publicly owned treatment works for similar reductions. Test 2 examines the cost effectiveness of additional industrial treatment beyond BPT. EPA must find that limitations are "reasonable" under both tests before establishing them as BCT. In no case may BCT be less stringent than BPT.

The complete Federal Water Pollution Control Act, including amendments under the Clean Water Act of 1977, is available in the form submitted to the Senate Committee on the Environment and Public Works:

FEDERAL WATER POLLUTION CONTROL ACT
Clean Water Act - Serial 95-12
Government Printing Office
Washington, DC

Attention is drawn to Section 101(f) of the Act:

"It is the National Policy that to the maximum extent possible, the procedures utilized for the implementing of this act shall encourage the drastic minimization of paperwork and inter-agency decision procedures and the best use of available manpower and funds, so as to prevent needless duplication and unnecessary delays at all levels of Government."

BILLS BEFORE CONGRESS

Clean Water Bill - James Howard (D-NJ), HR3282, 1983.
Clean Water Act, Amendment S-431 - Senator Chafee (R-RI), 1983.

U.S. FEDERAL REGULATIONS

Code of Federal Regulations = CFR, Title 40 - Environment

40 CFR, Part 257:
Under SWDA (1976) EPA Criteria for Sanitary Landfill. This regulation distinguishes legal disposal from "open dumping" which is prohibited by RCRA "non-hazardous waste" program.

40 CFR, Parts 260-271; May 19, 1980:
EPA Hazardous Waste Disposal Regulations, Implementing Section 3001 and Other Sections of RCRA, pp580-590.

40 CFR, Part 256:
EPA Guidelines for Solid Waste Management Plans.

40 CFR, Subchapter (N):
Effluent Guidelines and Standards - Part 415: Inorganic Chemical Manufacture; Part 421: Non-Ferrous Metals; Part 422: Phosphate; and Part 424: Ferro Alloys.

40 CFR, Subchapter (D):
Water Programs General - Pertinent to All Industries Listing Civil Penalties, Water Quality Regulations, NPDS System, State Program Requirements, Taxes on Effluent, Primary Drinking Water Standards, and Secondary Drinking Water Starndards.

40 CFR, Subchapter (J):
Solid Waste Disposal Act: RCRA.

40 CFR, Subchapter (I):
Hazardous Wastes, Parts 260-265; SWD Guidelines, Parts 240-257.

44 CFR, 44501, July 30, 1979:
Oil and Grease are defined by the EPA Administrator as "Conventional" and therefore subject to the Clean Water Act Section 304(a)4 and 301(b)(2)(E) subject to Best Conventional Pollution Control Technology (BCT).

44 CFR, 50732:
EPA published its methodology for carrying out BCT analysis.

40 CFR, 51722, 6 November, 1975:
EPA interim final regulations establishing BPT requirements for existing sources in the ore mining and dressing industry.

40 CFR, 51738; 6 November, 1975:
EPA proposed BAT, NSPS, and Pretreatment standards for ore mining and dressing.

41 CFR, 21191; 24 May, 1976:
EPA suspends parts of the interim final BPT regulations and solicits comments.

43 FR, 29711; 11 July, 1978:
EPA promulgates revised final BPT regulations for the Ore Mining and Dressing Industry.

44 FR, 7953; 8 February, 1979:
EPA published a clarification of the regulations as they apply to storm runoff.

44 FR, 11546; 1 March, 1979:
EPA amends final regulations by deleting the requirements for cyanide applicable to froth flotation mills in the base and precious metals subcategory.

U.S. Court of Appeals, 10th Cir., 10 December, 1979, Kennecott Copper Corp. vs. EPA, 612 F 2d 1232:
Upheld the BPT regulations rejecting challenges by five industrial petitioners.

Federal Register, 19 November, 1980, p76618:
Reports by EPA on various Mine and Metallurgical Wastes were due to be submitted by October, 1983. The Results of Assessment including Groundwater Monitoring of Waste Management at 8 Sites--"Study of Mineral Processing Waste," Section 8003(p) of the SWDA. "Mining and Milling Waste Study."

EPA (1982) Development Document for Effluent Limitations Guidelines and Standards for the Ore Mining and Dressing. Point Source Category, EPA 440/1-82/061, November 1982. "The BPT regulation provides for relief from effluent limitations including zero discharge during periods of precipitation. The basis of this upset or bypass (precipitation exemption) is that treatment facilities must be designed, constructed, and maintained to include the volume of water that would result from a 10-year, 24-hour precipitation event. The same provision is retained in BAT.

46 FR, 17567, 19 March, 1981:
EPA withdraws their proposed BAT, NSPS, and Pretreatment Standards.

14 June, 1982:
EPA proposed new BAT and NSPS standards and requested comments from the public.

47 FR, pp54598-54621, 3 December, 1982:
EPA promulgates final BAT and NSPS regulations for Ore Mining and Dressing, Point Source Category, Effluent Limitations. Guildelines and New Source Performance Standards.

NOTES ON REGULATION AND LICENSING OF MINING/MINERAL PROCESSING OPERATIONS IN CALIFORNIA

1. In California, mining and mineral processing waste has not been temporarily exempted from California laws regulating hazardous waste disposal.

2. Title 22 of the California Code of Regulations deals with hazardous waste management.

3. Matters relating to water quality fall under the jurisdiction of the California Water Board and the California State Government. The Porter-Cologne Act passed by the California state government defines the responsibilities of the California Water Board. There are overlapping responsibilities between California state and the California Water Board.

   The Hazardous Waste Management Branch of the California State Dept. of Health Services is responsible from the A1 soil zone up, and the Water Board is responsible for groundwater.

4. The California Occupational Safety and Health Administration regulates mine safety. The Hazardous Waste Management Branch becomes involved at the point of discharge of tailings at a mine-mill operation.

5. The Water Board is concerned with placer miners and any operation that could release silt or suspended solids to a stream.

6. The California Porter-Cologne Act has incorporated into it the federal National Pollutant Discharge Elimination System Act (NPDES).

7. In 1983, the California State Dept. of Health Services was trying to change the laws relating to mining and water to be similar to the federal laws but without the exemptions and using a modified EP toxicity test for determination of whether solid waste is hazardous or not. Within this structure, mine overburden would be exempted from jurisdiction by the State Dept. of Health Services but would be the responsibility of the Water Board.

8. Permits are required from the California State Regional Water Quality Control Board for all mine dumps. The California Regional Water Quality Control Boards examine all aspects of the operation that could have an impact on water quality.

9. Smaller placer mining operations employing up to 5-6 men are regulated by the California Fish and Game Dept.

10. Licensing fees are charged by the California State Dept. of Health Services. If over 500 acres are to be disturbed, the fee is $2,500. Between 50 and 500 acres, the fee is $5.00/acre. The minimum fee for less than five acres is $250.

11. The California Environmental Quality Act requires an Environmental Document. Effectively, this is an environmental impact statement on an operation which gets

circulated through a state clearing house to state authorities. All permit applications submitted at the county level are also sent via the clearing house to the state authorities.

It is the county's responsibility to inform the clearing house of all new operations. The county prepares the Environmental Document and issues one of three document types:

1) Exemption Certificate
2) A Negative Declaration - No Impact
3) An Environmental Impact Report

Items 2 and 3 are circulated through the state clearing house.

Although the county is responsible for the EIR, it usually hires consultants to carry them out. For example, the EIR on the Homestake Mining Company's McLaughlin Mine was prepared by:

ENGINEERING SCIENCE, INC.
Berkeley, CA

The consultants submit their fee to the mining company.

12. According to Dr. Takashi Asano:

OFFICE OF WATER RECYCLING
California State Water Research
Control Board
Post Office Box 2000
Sacramento, CA 95810

There are no guidelines for the recycling of water by the mining industry which in California is a minor user of water compared to other industries.

13. The Homestake Mining Company had to apply for over 281 permits for the McLaughlin operation, many of which directly or indirectly related to water management, e.g.:

- <u>Dam Approvals</u> — California Dept. of Water Resources, Divison of Dam Safety
- <u>Hazardous Waste Facility Permit</u> — California Dept. of Health Services
- <u>Solid Waste Disposal Facility Permit</u> — Lake County Solid Waste Board

° <u>Waste Discharge Requirement and NPDES Permit</u>	Central Valley Regional Water Quality Control Board (National Pollution Discharge Elimination System)
° <u>Water Appropriation</u>	State Water Resources Control Board
° <u>Stream Alteration Agreement</u>	California Dept. of Fish and Game

At the NORANDA Grey Eagle Mine at Happy Camp in northern California, the Regional Water Quality Control Board issued a cease and desist order when the company reported to them that a minor seepage of cyanide had been detected from the tailings dam. If the terms of the cease and desist order cannot be met, the case would be referred to the California Attorney General for prosecution. Fines up to $5,000/day can be imposed.

California Regional Water Quality Control Board
North Coast Region

ORDER NO. 84-108

WASTE DISCHARGE REQUIREMENTS

for

NORANDA, INC.
NORANDA GREY EAGLE MINES, INC.,
AND
SISKON CORPORATION

Siskiyou County

The California Regional Water Quality Control Board, North Coast Region, finds that:

1. On April 30, 1981, the Regional Board adopted Board Orders 81-51, 81-52, and 81-53, Waste Discharge Requirements for overall mine and mill activities, treated wastewater disposal activities, and tailings disposal activities, respectively. The adopted Orders reflect mining, milling, and waste disposal activities described in reports of waste discharge submitted by Mr. Steven A. Wulf, Vice President of Noranda Grey Eagle Mines, Inc., on January 19, 1981. On December 3, 1981, the Board adopted Order No. 81-222 amending Order No. 81-53 to provide financial assurances for closure and post closure activities regarding the tailings reservoir hazardous waste disposal facility. On May 31, 1984, the Board adopted Order No. 84-49, Waste Discharge Requirements, for tailings dam seepage control facilities.

2. Noranda Grey Eagle Mines, Inc., a Delaware Corporation, is a wholly owned subsidiary of Noranda, Inc., a Delaware Corporation. Noranda, Inc., is a wholly owned subsidiary of Noranda Manufacturing Inc., of Toronto, Ontario, Canada. Noranda Manufacturing Inc., is a wholly owned subsidiary of Noranda Inc., of Toronto, Ontario, Canada.

3. Siskon Corporation is the owner of patented and unpatented claims on which the Grey Eagle Mine is located. Noranda Grey Eagle Mines, Inc., is the sole owner of the lease to these claims. Noranda, Inc. (the owner of Noranda Grey Eagle Mines, Inc.), Noranda Grey Eagle Mines, Inc., and Siskon Corporation are hereinafter referred to as the discharger.

4. The Grey Eagle Mine is located within Section 14, T17N, R7E, HB&M in the watershed of Luther Gulch, tributary to Indian Creek thence the Klamath River in Siskiyou County. The mine is five miles north of Happy Camp. Facilities for treating wastewater and disposing of treated wastewater are located within Sections 14 and 11, T17N, R7E, HB&M in the watershed of Luther Gulch and Baker Gulch, both tributary to Indian Creek, thence Klamath River in Siskiyou County. The treatment and disposal sites are approximately five and six miles north of Happy Camp.

5. The Grey Eagle Mine, prior to the entry of NGEMI, was a continuous and chronic source of acid mine drainage which emanated from tunnels and waste

ore dumps remaining from its days of operation as a copper mine - concentrating mill during World War II. Acidic, dissolved metals-bearing drainage was toxic to all aquatic life in Luther Gulch Creek. The discharger has taken measures to reduce the effects of acid mine drainage. Measures include the sealing and flooding of tunnels and removal of waste rock from the stream system.

6. The Noranda Grey Eagle Mine is an open pit gold and silver mine. The overburden removed to expose the ore body was used to construct a tailings dam. The ore is processed at a carbon-in-pulp/cyanide leach mill and untreated tailings are discharged to the tailings dam reservoir for permanent disposal. Excess wastewater which accumulates in the tailings reservoir is treated and pumped to remote percolation basins for disposal. Pursuant to mining, milling, and waste disposal activities, the discharger has constructed:

   a. Mill and services buildings
   b. Open pit
   c. Tailings dam
   d. Diversion channel around tailings reservoir
   e. Tailings reservoir seepage control facilities
   f. Wastewater treatment facilities
   g. Export pipeline
   h. Land application site for treated wastewater
   i. Site roads
   j. On-site drainage facilities
   k. Topsoil storage site

7. Erosion control work to prevent discharge of earthen materials to surface drainages is performed by the discharger in accordance with reports submitted annually to the Regional Board.

8. The discharger receives, stockpiles, and uses in the mining-milling and waste treatment processes a number of hazardous or potentially hazardous raw materials and process chemicals including:

Material	On-Hand	Usage Rate (Resupply)
Chlorine	18 tons	5.5 tons/day
Lime	25 tons	150 tons/month
Lime Hydrate	10 tons	4 tons/month
Sodium Cyanide	20 tons	30 tons/month
Fuel Oil	5,000 gallons	6,000 gal/month
Acid (HCl)	2 drums	2 drums/year
Acid (Nitric)	5 drums	5 drums/year
Polyphosphate	5 drums	165 gal/month
Sodium Hydroxide	20,000 lb	10,000 lb/day
Polyacrilamide	5 tons	1.5 tons/month
Gasoline	2,000 gallons	3,000 gal/month

The discharger has submitted a contingency and spill prevention plan dated September, 1984, which describes spill prevention, containment, and cleanup measures.

9. The discharger has described sources of waste and wastewater from operations at the Noranda Grey Eagle Mine which include:

	Waste	Quantity	Disposal
a.	Process tailings slurry (solid and liquid phase)	650 ton/day (solid) 0.17 mgd (liquid)	tailings reservoir
b.	Treated wastewater effluent	0.35 mgd	land application site
c.	Wastewater treatment sludges	5 tons/month	tailings reservoir
d.	Tailings reservoir seepage	35 gpm	tailings reservoir
e.	Domestic waste (toilet)	1 gpm	leachfield
f.	Non-toilet domestic waste	5 gpm	tailings reservoir
g.	Mill site runoff	52 gpm (storm)	tailings reservoir
h.	Other site runoff	unknown	sedimentation ponds/ surface drainages

10. Facilities for treating excess wastewater in the tailings reservoir include the following unit processes:

a. chlorine oxidation
b. hydroxide precipitation
c. flocculant addition
d. sedimentation

The design capacity of the wastewater treatment plant was originally estimated at 159 gpm but improvements installed since the plant was constructed has enabled flow rates up to 400 gpm to be achieved.

Self-monitoring reports submitted by the discharger and verified by Regional Board staff indicated that water quality constituents which are present in the excess wastewater at levels of concern include:

a. cyanide
b. copper
c. iron
d. zinc

e. cadmium
f. lead
g. mercury
h. nickel

Performance records at the treatment plant indicate that treated effluent consistently attains State and/or EPA drinking water standards for all constituents with occasional exception of mercury. Process adjustments necessary to further reduce mercury levels have been shown to affect effluent levels for other constituents such that overall effluent quality is adversely affected.

The treated effluent typically exhibits high salt levels and alkaline pH.

The discharge of treated wastewater has been shown to increase salt levels in ground and surface waters of Baker Gulch, the affected drainage. This increase has not been shown to adversely impact beneficial uses of these waters.

11. The discharger has constructed the tailings dam and reservoir with the following dimensions:

a. height above cutoff trench — 240 feet
b. crest length — 950 feet
c. volume of fill — 2.5 million cubic yards
d. reservoir volume — 900 acre-feet
e. reservoir surface area (16 acres)
f. flood protection — 3 feet of freeboard above 2500 year recurrence rainfall event (190 acre-feet)

The dam has been built with special features, including:

a. Core — upstream face, compacted clays selected from suitable deposits on site. The core zone is anchored in a cutoff trench excavated to competent bedrock. Function is to control movement of water through dam.

b. A grout curtain was installed in bedrock underlying the core to impede migration of pollutants under the dam.

c. Chimney and blanket drain — behind core and above foundation area, imported drain rock. Function is to control movement of water through dam.

d. Random fill - structural embankment extending up to 1,300 feet downstream of chimney drain, overburden and waste rock from mining site.

e. Coarse rock armour — selected rock to protect fill from surface erosion, selected from random fill zone.

f. Clay plug - interior of dam, compacted clays selected to impound and divert tailings reservoir seepage from the chimney drain via discharge pipes which emerge at the toe of dam.

g. Diversion system - face of dam equipped with drainage control system to divert runoff and minimize infiltration.

h. Pumpback system — consists of a slurry wall, wet well, and pumping station at toe of dam to contain, collect, and return tailings reservoirs seepage to the reservoir.

12. The discharger has constructed an extensive diversion works which removes all runoff from the watershed above the reservoir and transports it to the North Fork Luther Gulch stream channel below the tailings dam. This diversion is covered by an appropriative water right filing, State Board Application No. 26450. The diversion and conveyance structures are sized to control a 2500-year storm runoff rate to assure that such flows will not enter the reservoir.

13. The design and construction of the tailings dam, reservoir, and diversion works described are subject to regulatory jurisdiction of the California Department of Water Resources, Division of Dam Safety (DDS). A certificate to impound water was awarded by DDS on November 14, 1983.

14. Wastes discharged to the tailings reservoir include water and soluable (dissolved) residues from various waste streams and solids which consist largely of gangue (unreacted minerals from mining/mill processes) and sludges from water and wastewater treatment facilities.

The discharger has reported that, on a daily average basis, 650 tons per day of solid phase and 0.17 mgd of water phase is discharged to the tailings reservoir. At the end of mining and ore processing activities, the discharger estimates that 560 acre-feet of tailings will be accumulated. The discharger has submitted reports which confirm the presence of the following constituents in the water phase:

Heavy metals (as cations or components of complexes) - Cu, Fe, Zn, Pb, Na, Hg, Ni, Al and traces of As and Cd

Cations - Na, Ca, Mg, K

Non-metals (as anions or components of complexes) - $SO_4^{=}$, Cl^-, HCO_3^-, $CO_3^{=}$ cyanide (free and complexed) thiocyanate

15. The discharger has reported the quantities and qualities of solid and liquid wastes which have been continuing to be discharged to, recycled from, removed for treatment and disposal off-site, and retained as solid waste in the tailings reservoir. These wastes contain dissolved and/or soluble components such as heavy metals and free and complexed cyanides which, if discharged to surface waters or usable groundwaters, would adversely affect the quality of those waters. The waste is a Group 1 waste as classified in Section 2520 of the California Administrative Code, Title 23 - Waters.

16. The tailings dam and reservoir is a hazardous waste disposal facility as defined by California Administrative Code, Title 22, and permitted by California Department of Health Services (DOHS). A Hazardous Waste Facility Permit was issued by DOHS on April 20, 1982.

17. The discharger has constructed control facilities at the toe of the tailings dam to impound and return tailings reservoir seepage back to the reservoir. The seepage contains pollutants which originate in the tailings reservoir. Control facilities consist of an impermeable slurry trench excavated to bedrock to impound underground flows, a wet well with french drains to collect the seepage, three pumps (lead, backup, and standby), auxiliary power source, and export pipeline to the tailings reservoir/wastewater treatment plant.

18. The discharger has partially constructed seepage treatment and disposal facilities for long term control of tailings reservoir seepage. The facility employs the alkaline-chlorine process and when completed will consist of chemical storage, reactor vessels, clarification, sand filtration, and pH adjustment with discharge by gravity to percolation beds adjacent to Indian Creek. The discharger has demonstrated that the existing wastewater treatment facility in conjunction with the seepage control facilities is capable of processing all anticipated flows until termination of ore-processing activities when the tailings reservoir will be reclaimed. Therefore, long term seepage treatment and control facilities will not be activated until mining and milling activities are terminated.

19. The discharger's description of natural and man-made features which prevent lateral and vertical continuity between liquids in the waste and surface waters meets the criteria for classification as a Class II-1 disposal site as established in Section 2511 of the California Administrative Code, Title 23 - Waters. Section 2532 of said Code provides that the disposal of certain Group 1 wastes may be allowed in a Class II-1 site by a regional board, when in the judgment of the board, such disposal will not unreasonably affect water quality. Such restricted disposal of specific Group 1 wastes shall be subjected to terms and conditions considered appropriate by the Regional Board.

20. The discharger submitted an operations plan with the original reports of waste discharge on January 19, 1981. These documents contain analyses of alternative methods of site closure.

    The report of waste discharge and operations plans describe the activities which will occur after the mining operations terminate. Excess stored water will be treated and discharged to the off-site percolation beds and the solid phase wastes will be allowed to consolidate. A gravel layer will be placed over the tailings to bar upward capillary movement of water. A compacted clay cap will be placed over the gravel and tailings to bar downward movement of rainfall. A layer of topsoil (stockpiled during the

initial mine-mill development) will be placed over the clay cap and revegetated with native plants to prevent erosion of the clay cap and top soil material. Monitoring and periodic maintenance/repair will be provided.

In September and October, 1981, the discharger submitted estimates of costs for site closure and post-closure monitoring and maintenance assurances of financial responsibility for closure and post-closure activities.

On January 15, 1984, the discharger submitted a report of waste discharge and revised Operation Plan to reflect the necessity of constructing long term seepage treatment and disposal facilities. Detailed cost estimates for operation and maintenance of these facilities were submitted on May 8, 1984.

Final cost estimates for all closure and post closure activities were submitted on _____, 1984, in the amount of $_____.

Exhibit A, appended and hereby made a part of this Order is a summary of the estimated costs of closure and post-closure activities.

Exhibit B, appended and hereby made a part of this Order is a copy of a statement which describes the financial condition of Noranda Inc., of Toronto, Canada.

Exhibit C, appended and hereby made a part of this Order is Guarantee by Noranda, Inc., in favor of the State of California, Regional Water Quality Control Board, North Coast Region, on behalf of Noranda Grey Eagle Mines, Inc., whereby Noranda Inc., guarantees that it will assume the financial responsibility for closure, reclamation and monitoring of the Grey Eagle Mine tailings disposal site in the event that Noranda Grey Eagle Mines, Inc., fails to comply with Regional Board Orders.

21. The Regional Board adopted the Water Quality Control Plan for the Klamath River Basin (1A) on March 20, 1975, and last amended in September 1983.

22. Beneficial uses of waters of the Klamath River Basin include:

    a. municipal and agricultural water supply
    b. industrial water supply
    c. groundwater recharge
    d. freshwater replenishment of lakes and streams
    e. hydropower generation
    f. water contact and non-water contact recreation
    g. warm freshwater habitat
    h. cold freshwater habitat
    i. wildlife habitat
    j. migration route for anadromous fish
    k. fish spawning area.

23. In order to protect the beneficial uses of the Klamath River Basin, the Basin Plan prohibits the discharge of waste to all surface, freshwater

impoundments, and their tributaries, with the exception of the Lower Lost River system.

24. On October 28, 1968, the State Water Resources Control Board adopted Resolution No. 68-16, the Non-Degradation Policy. The Policy provides that:

    a. Whenever the existing quality of water is better than the quality established in policies as of the date on which such policies become effective, such existing high quality will be maintained until it has been demonstrated to the State that any change will be consistent with maximum benefit to the people of the State, will not unreasonably affect present and anticipated beneficial use of such water and will not result in water quality less than that prescribed in the policies; and

    b. Any activity which produces or may produce a waste or increased volume or concentration of waste and which discharges or proposes to discharge to existing high quality waters will be required to meet waste discharge requirements which will result in the best practicable treatment or control of the discharge necessary to assure that (a) a pollution or nuisance will not occur and (b) the highest water quality consistent with maximum benefit to the people of the State will be maintained.

25. The Board has notified the discharger and interested agencies and persons of its intent to prescribe waste discharge requirements for this discharge.

26. The discharger has stated and the Board finds that all local agencies with jurisdiction has approved use of the site for the intended purposes.

27. The County of Siskiyou, in accordance with the California Environmental Quality Act, has prepared and circulated the following:

    •Notice of Preparation; May 15, 1980
    •Draft Environmental Impact Report; August, 1980
    •Supplement to Draft EIR — Comments and Responses; October 1, 1980

    The County Use Permit, issued October 27, 1980, requires conformance with state/local/federal regulations.

    The United States Klamath National Forest has prepared Environmental Assessments related to various project elements as follows:

    • Road Improvements, Environmental Assessment dated September 9, 1980. Operations Plan for Noranda Mining Operations on Public Lands, Environmental Assessment dated February 9, 1981.

    • Seepage treatment and disposal facilities, Finding of No Significant Impact dated April 24, 1984.

28. The Regional Board has determined that compliance with the provisions contained in these requirements will mitigate the potential adverse water quality impacts identified in the Environmental Impact Report.

29. The Board in a public hearing on October 25, 1984, in Rohnert Park, California, heard and considered all comments pertaining to the discharge.

THEREFORE, IT IS HEREBY ORDERED THAT Board Orders 81-51, 81-52, 81-53, 81-222, and 84-49 are hereby rescinded and that Noranda, Inc., and Noranda Grey Eagle Mines, Inc., shall comply with the following:

A. DISCHARGE PROHIBITIONS

1. There shall be no discharge of treated or untreated domestic sewage, industrial waste; runoff from ore stockpiles, or process chemical storage/receiving areas; or other solid waste or any deleterious material to the surface waters of the Klamath River Basin.

2. There shall be no discharge of any waste except domestic (toilet and urinal) to septic tank/leachfield treatment/disposal facilities.

3. The creation of a nuisance or a pollution, as defined in Section 13050 of the California Water Code, as a result of any waste collection, treatment, and disposal is prohibited.

4. There shall be no discharge of soil, silt, bark, slash, sawdust, or other organic and earthen material from any logging, construction, or associated activity of whatever nature into any stream or watercourse in the basin in quantities deleterious to fish, wildlife, or other beneficial uses.

5. There shall be no placing or disposal of soil, silt, bark, slash, sawdust, or other organic and earthen material from any logging, construction, or associated activity of whatever nature at locations where such material could pass into any stream or water course in the basin in quantities which would be deleterious to fish, wildlife, or other beneficial uses.

B. EFFLUENT LIMITATIONS

1. Treated industrial process wastewaters discharged to the land disposal site shall meet the following limits:

Constituent	Units	Maximum Concentration
Arsenic	mg/l	0.002
Copper	mg/l	0.20
Iron	mg/l	0.20
Cyanide (free)	mg/l	0.02
Zinc	mg/l	0.01

Constituent	Units	Maximum Concentration
Lead	mg/l	0.05
Nickel	mg/l	0.40
Cadmium	mg/l	0.01
Mercury	mg/l	0.002
Aluminum	mg/l	0.5
pH	pH units	6.5 - 7.5

C. PROVISIONS

1. The discharger shall comply with the Contingency Planning and Notification Requirements, Order No. 74-151 and the Monitoring and Reporting Program No. 84-108 and the General Provisions for Monitoring and Reporting, and any modifications to these documents as specified by the Executive Officer. Such documents are attached to this Order and incorporated herein.

2. The discharger shall submit a report of waste discharge to the Regional Board at least 120 days before initiating any new discharge or making any material change in the character, location, or volume of any waste discharge.

3. The discharger shall protect from erosion all disturbed soil areas, protective dikes, diversion facilities, stream crossings, and other water quality control facilities.

4. The discharger shall provide proper sanitary facilities at appropriate locations in project construction areas. The design, installation, and use of any domestic waste disposal system shall be in compliance with any and all more restrictive Siskiyou County health ordinances and regulations.

5. Collected screenings, sludges, and other solids removed from liquid wastes shall be disposed of at a legal point of disposal, and in accordance with the provisions of Division 7.5 of the California Water Code. For the purpose of this requirement, a legal point of disposal is defined as one for which waste discharge requirements have been prescribed by a regional water quality control board and which is in full compliance therewith.

6. The discharger shall maintain in good working order and operate as efficiently as possible any facility or control system installed by the discharger to achieve compliance with the waste discharge requirements.

7. In the event the discharger is unable to comply with any of the conditions of this Order due to:

   a. breakdown of waste treatment equipment;
   b. accidents caused by human error or negligence; or
   c. other causes such as acts of nature;

   the discharger shall notify the Executive Officer by telephone as soon as he or his agents have knowledge of the incident and confirm this notification in writing within two weeks of the telephone notification. The written

notification shall include pertinent information explaining reasons for the noncompliance and shall indicate what steps are taken to correct the problem and the dates thereof, and what steps are being taken to prevent the problem from recurring.

8. The requirements prescribed herein do not authorize the commission of any act causing injury to the property of another, nor protect the discharger from his liabilities under federal, state, or local laws.

9. The discharger shall permit the Regional Board:

   a. Entry to the project area and upon premises in which a waste source or waste discharge is located or in which any required records are kept;

   b. Access to copy any records required to be kept under terms and conditions of this Order;

   c. Inspection of monitoring equipment or records; and

   d. Sampling of any discharge.

10. The discharge of any pollutant not identified and authorized by the waste discharge requirements or the discharge of any pollutant in a manner or quantity which differs from that stated in the report of waste discharge is prohibited.

11. The discharger shall implement the contingency and spill prevention, containment, and planning measures as described in the report entitled "Hazardous Material Spill Prevention and Preparedness Plan" dated September 1982, updated November 1983. This report shall be updated annually and submitted to the Executive Officer. Failure to comply with these measures is a violation of this Order.

12. In the event of any change in control or ownership of land or waste discharge facilities presently owned or controlled by the discharger, the discharger shall notify the succeeding owner or operator of the existence of this Order by letter, a copy of which shall be forwarded to this Board.

13. Group 1 waste materials shall not be disposed of outside of the tailings reservoir.

14. The Group 1 waste disposal area shall be protected from any washout or erosion of wastes or covering material, and from inundation, which could occur as a result of floods having a predicted frequency of once in 2500 years.

15. The discharge of Group 1 wastes to the tailings reservoir shall be limited to the materials produced by the discharger in the cyanide processing of gold and silver ores from the Grey Eagle Mine.

16. Group 1 waste materials and any water that has contacted the waste shall be contained in the area designed for Group 1 wastes including seepage control facilities.

17. A minimum freeboard of three feet shall be maintained in the tailings reservoir at all times.

18. Waste confinement barriers shall be protected and maintained to ensure their effectiveness.

19. All site facilities used to contain Group 1 waste shall be designed and constructed to minimize damage to the graded foundation or the structures which control leachate, surface drainage, erosion and gas due to the maximum credible earthquake.

20. There shall be no overflow from the waste holding facilities used for Group 1 waste.

21. A leachate collection and disposal system shall be constructed and maintained downgradient from the disposal area to prevent any leachate or other liquid waste from entering ground or surface water. Leachate volumes contained by liquid control barriers shall be maintained below a volume equal to 75 percent (or a lesser amount if necessary because of specific site conditions) of the total liquid storage capacity of the barrier.

22. The leachate control facility shall consist of at least two feet of compacted clay, soil cement (having a permeability of 1×10^{-6} cm/sec or less), or other equivalent material approved by the Executive Officer. The thickness of the barrier must be based on the anticipated life of the site and the threat of the specific waste to the beneficial use of the waters of the basin.

23. Long term tailings reservoir seepage treatment and disposal facilities shall be completed and operable within three months of terminating ore processing activities.

24. The discharger shall maintain a copy of this Order at the site so as to be available at all times to site operating personnel.

25. The discharger shall file with this Board an updated operation plan when substantial changes in operations are made. A letter indicating conformance with existing plans shall be submitted annually. For the purpose of these requirements, this includes any proposed change in the boundaries, contours, or ownership of the disposal area.

26. The owner or operator of the disposal site shall provide assurances that monies are available in an amount estimated by the Board to be sufficient to ensure the closure and subsequent post closure maintenance of the disposal site in a manner that will not pose an adverse threat to the environment. The cost estimate and, if necessary, the financial assurances shall be updated on an annual basis. Post closure maintenance costs shall be estimated for a period of thirty years following site closure.

27. The dischargers shall comply with provisions of the water right permit issued by the State Water Resources Control Board pursuant to Application No. 26450. Failure to comply is a threatened violation of this Order.

28. The dischargers shall comply with requirements of the California Department of Water Resources, Division of Dam Safety. Failure to comply is a threatened violation of this Order.

29. The dischargers shall comply with all permits issued by the Department of Health Services. Failure to comply is a threatened violation of this Order.

30. The discharger shall implement the Reclamation Plan as approved and as may be revised by County of Siskiyou. Failure to implement the Reclamation Plan is a threatened violation of this Order.

Certification

I, David C. Joseph, Executive Officer, do hereby certify that the foregoing is a full, true, and correct copy of an Order adopted by the California Regional Water Quality Control Board, North Coast Region, on October 25, 1984.

_____

David C. Joseph
Executive Officer

California Regional Water Quality Control Board
North Coast Region

MONITORING AND REPORTING PROGRAM NO. 84-108

FOR

NORANDA GREY EAGLE MINES, INC.

Siskiyou County

MONITORING - WATER QUALITY

Grab samples shall be collected at monitoring stations listed below and described on Attachment "A" and analyzed as follows:

STATION	LOCATION	ANALYSES*	FREQUENCY
1.	South Fork Luther Gulch Above Tailings Reservoir	—	Discontinue Sampling
2.	North Fork Luther Gulch above South Fork Confluence	—	Discontinue Sampling
3.	Luther Gulch Below Toe of Tailings Dam	A B	Monthly Quarterly
4.	Luther Gulch at Green Gate	—	Discontinue Sampling
5.	Luther Gulch Above County Road Crossing	—	Discontinue Sampling
6.	Indian Creek 100 feet above Luther Gulch Confluence	—	Discontinue Sampling
7.	Indian Creek 100 feet below Luther Gulch Confluence	—	Discontinue Sampling
8.	Indian Creek 1.3 miles below Luther Gulch	—	Discontinue Sampling
9.	Tailings Reservoir (Return Line)	A, B,	Monthly
10.	Monitoring Well South Abutment of Dam	A	Quarterly

STATION	LOCATION	ANALYSES*	FREQUENCY
11.	Monitoring Well North Abutment of Dam	A	Quarterly
12.	Chimney Drain North Discharge Pipe (D2)	A B	Monthly Quarterly
13.	Chimney Drain South Discharge Pipe (D2)	A B	Monthly Quarterly
14.	Blanket Drain Discharge at Toe of Dam (D4)	A B	Monthly Quarterly
15.	Monitoring Well at Toe of Dam	A B	Monthly Quarterly
16.	Spring Below Land Application Site	A, B	Monthly
17.	Water Treatment Plant Effluent	A, B	Monthly
18.	East Monitoring Well at Land Application Site	A, B	Quarterly
19.	Southwest Monitoring Well at Land Application Site	A, B	Quarterly
20.	North Monitoring Well at Land Application Site	A, B	Quarterly
21.	West Well at Proposed Indian Creek Perc Field	EC, TDS, TCN	Quarterly
22.	South Well at Proposed Indian Creek Perc Field	EC, TDS, TCN	Quarterly
23.	East Well at Proposed Indian Creek Perc Field	EC, TDS, TCN	Quarterly

* Group A analyses = Total cyanide, free cyanide, copper, iron, zinc, sulfate, chloride, sodium, pH, EC, and TDS
Group B analyses = arsenic, cadmium, lead, mercury, nickel, aluminum

FLOW/LEVEL MONITORING

Static levels in groundwater monitoring wells shall be recorded at the time of sample collection. Flow rate shall be measured at Stations 12, 13, 14, and the road crossing (water hole) on Luther Gulch Creek at the approximate time of sample collection.

Flow rate for the pumpback system shall be recorded daily.

Reservoir volume, remaining capacity, and static elevation of surface shall be recorded weekly.

MONITORING - EROSION CONTROL

The discharger shall observe and record erosion/slope stability problems and sediment control basin performance. Monitoring records shall be related to storm events.

REPORTING

Monitoring reports shall be submitted to the Regional Board for each month by the 15th day of the following month. Reports shall include results from all water quality analyses performed and shall be signed by a responsible official of Noranda Grey Eagle Mines, Inc. The report shall include a detailed narrative summary of erosion control monitoring during the month and a description of proposed corrective measures implemented or proposed. The erosion control monitoring summary shall be supplemented with photographs as necessary to accurately describe both problems and corrective measures.

CALIFORNIA REGIONAL WATER QUALITY CONTROL BOARD
CENTRAL VALLEY REGION

ORDER NO. _____

NPDES NO. CA0081477

WASTE DISCHARGE REQUIREMENTS
FOR
McLAUGHLIN MINE
HOMESTAKE MINING COMPANY
AND
US BUREAU OF LAND MANAGEMENT
YOLO, LAKE AND NAPA COUNTIES

The California Regional Water Quality Control Board, Central Valley Region (hereafter Board), finds that:

1. Homestake Mining Company (hereafter Discharger) submitted a report of waste discharge, dated 15 April 1983, to discharge waste under the National Pollutant Discharge Elimination System.

2. The proposed mining operation will operate in part on public lands administered by the US Bureau of Land Management (hereafter Discharger).

3. The Discharger proposed to discharge water in contact with mine activities from five sedimentation ponds into Hunting Creek and Knoxville Creek, both tributary to Lake Berryessa, a water of the United States.

4. Homestake Mining Company proposes to develop a gold mine and mineral extraction facility (mill) to process about 4000 tons of ore per day. Units of the mine include: mine pit, waste rock site, grinding and crushing area, mill, low grade ore storage, slurry line, tailings disposal facility, water supply reservoir, interconnecting roadways and electrical transmission corridor.

5. The mining process will begin at an open pit mine which will ultimately be one mile long, one-half mile wide and 400 feet deep. Higher grade ore bearing rock will be crushed, ground and piped through a 4-1/2 mile slurry pipeline to the mill site. Waste rock from the mine pit will be disposed of on 342 acres some of which are public lands administered by the US Bureau of Land Management. The pipeline slurry will undergo a cyanide leach process to extract gold at the 35 acre mill site. Processed slurry will be discharged to the 546 acre tailings disposal facility.

6. The discharge to land of all mining activities, including the tailing disposal reservoir, is regulated through separate waste discharge requirements.

7. The report of waste discharge describes the water discharge as follows:

Pond	Discharge Point Serial Number	Description
T_1	001	Sediment trap for topsoil stockpile taken from the tailings reservoir. T_1 will function primarily during the first three years before the topsoil is revegetated and again towards the end of project during the reclamation phase. During most of the operating life of the project, the sediment yield to the pond is expected to be minimal. The pond will be maintained for the entire project and reclamation period.
T_2	002	Same as pond T_1.
W_1	003	Sediment trap for the waste rock disposal facility from stormwater runoff and waste rock subdrainage. This pond will be required for the life of the project.
W_2	- -	Sediment trap within the waste rock disposal facility. This pond may or may not be required. If constructed, it would flow only into pond W_1, and therefore would not be an NPDES discharge point.
M_1	004	Sediment trap for the grinding facility area during the mine construction period only (i.e., the first 1 to 2 years). Thereafter, the pond will be used as a water-recycling pond and will not be an NPDES discharge point.
M_2	005	Sediment trap for the early years of development at the south pit. This pond will be required for approximately the first 7 years of mining. Thereafter, all runoff from pit disturbance will be contained within the pit and the pond decommissioned.

8. The Board, on 25 July 1975, adopted a Water Quality Control Plan for the Sacramento River Basin (5A). These requirements are consistent with the Plan.

9. The beneficial uses of Lake Berryessa are municipal, industrial, and agricultural supply; recreation; esthetic enjoyment; navigation; ground water recharge; fresh water replenishment; hydroelectric power generation; and preservation and enhancement of fish, wildlife and other aquatic resources.

10. The beneficial uses of the ground water downstream of the project are municipal and agricultural supply.

11. The chemical quality of the ground and surface waters in the immediate vicinity of the tailings disposal facility and the waste rock disposal facility is generally poor, when compared to EPA Primary and Secondary Drinking Water Standards. Boron levels frequently exceed the recommended levels for continuous irrigation use.

12. Effluent limitation standards established pursuant to Sections 301, 302, and 304 of the Federal Water Pollution Contol Act and amendments thereto are applicable to the discharge.

13. On 6 July 1983, the Napa County Planning Commission certified the final Environmental Impact Report/Environmental Impact Statement (EIR/EIS) for the Homestake Mining Company McLaughlin Gold Project in accordance with the California Environmental Quality Act (CEQA) Public Resources Code Sections 21000, et seq. The EIR/EIS discloses that the project may have the following significant impacts on water quality:

    a. Increased erosion during construction.

    b. Landslides along the perimeter of the water reservoirs.

    c. Increased sedimentation to streams during construction.

    d. Increased TDS and heavy metals concentration to Hunting Creek downstream of the waste rock dump.

    e. Contamination of Hunting Creek from accidental spills of mill reagents or tailings disposal facility rupture.

14. The Board has reviewed the EIR/EIS. These waste discharge requirements provide protection to water quality equal to or more effective than the mitigation measures in the EIR/EIS relating to water quality. Compliance with these waste discharge requirements will mitigate or avoid the following significant impacts on water quality listed in Finding 13:

    a. Landslides along the perimeter of the water reservoir. Mitigation of this potential impact is required by turbidity, sedimentation and erosion controls contained in these requirements.

    b. Increased TDS and heavy metals concentration to Hunting Creek downstream of the waste rock dump. Mitigation of this potential impact is accomplished by receiving water limitations on heavy metals and the requirement to implement best available technology (BAT) to limit mineralization.

15. The following impacts will be mitigated to some extent by these requirements, but the EIR/EIS identifies these as unavoidable potentially significant environmental impacts:

    a. Increased erosion during construction.

b. Increased sedimentation to streams during construction.

c. Contamination of Hunting Creek from accidental spills of mill reagents or tailings disposal facility rupture.

While these significant detrimental impacts may occur, the Board finds these impacts are outweighed by the potential benefits of the project. This decision is based on the two potential benefits to water quality listed in the EIR/EIS:

a. Long-term improvement to Knoxville Creek water quality downstream of mine pit due to the ultimate elimination of poor quality runoff from the mine pit area.

b. Long-term reduction in sedimentation to Davis Creek downstream of the reservoir through dam releases of better-quality water than that presently existing.

16. Subsequent to the preparation of the final EIR/EIS, Discharger and the Solano Irrigation District (SID) entered into an Agreement (the SID Agreement) which provides for a comprehensive monitoring program and a series of response mechanisms designed to preclude any potential adverse environmental impacts on water quality which might otherwise occur in connection with the project. Pursuant to the SID Agreement, Discharger has agreed to comply with specified requirements in order to assure nondegradation of the water quality of any surface or subsurface waters flowing or draining into or through Hunting, Soda, Knoxville, Putah or Eticuera Creeks into Lake Berryessa.

17. The Board has notified the Discharger and interested agencies and persons of its intent to prescribe waste discharge requirements for this discharge and has provided them with an opportunity for a public hearing and an opportunity to submit their written views and recommendations.

18. The Board, in a public meeting, heard and considered all comments pertaining to the discharge.

19. This Order shall serve as a National Pollutant Discharge Elimination System permit pursuant to Section 402 of the Federal Water Pollution Control Act, or amendments thereto, and shall take effect ten days from the date of hearing, provided EPA has no objections.

IT IS HEREBY ORDERED, Homestake Mining Company and the property owner, in order to meet the provisions contained in Division 7 of the California Water Code and regulations adopted thereunder and the provisions of the Federal Water Pollution Control Act and regulations and guidelines adopted thereunder, shall comply with the following:

A. Prohibitions:

1. The discharge of domestic sewage, industrial wastes and runoff from ore stockpiles and process chemical storage/receiving areas, which is deleterious to fish, wildlife or other beneficial uses, is prohibited.

B. Effluent Limitations:

1. The discharge of an effluent in excess of the following limits is prohibited:

Constituents	Units	30-Day Average	Daily Maximum
Suspended Solids	mg/l	20	30
Settleable Solids	ml/l	1.0	5.0
Arsenic	mg/l	0.05	0.10
Cadmium	mg/l	0.01	0.02
Chromium	mg/l	0.05	0.10
Copper	mg/l	0.15	0.30
Mercury	mg/l	0.001	0.002
Lead	mg/l	0.05	0.10
Zinc	mg/l	0.75	1.5

Metals shall be analyzed and reported as totals.

2. The discharge shall not have a pH less than 6.5 nor greater than 9.0.

3. The Discharger shall use the best available technology to limit mineralization to no more than a reasonable increment.

4. Discharge to surface waters shall be limited to discharge from the sediment control ponds.

C. Receiving Water Limitations:

1. The Discharger shall not cause the dissolved oxygen concentration in Hunting or Knoxville Creek to fall below 5.0 mg/l.

2. The discharge shall not cause visible oil, grease, scum, foam, floating or suspended material in the receiving waters or watercourses.

3. The discharge shall not cause a measurable increase, over upstream levels of the receiving waters, of the following constituents: Arsenic, Lead.

4. The discharge shall not cause a statiscally significant, incremental increase of more than 10% (or, if greater than 10%, the minimum percentage increase that may be accurately measured) over upstream levels of the receiving waters, of the following constituents: Mercury, Chromium, Cadmium, Boron, Copper, Nickel.

5. The discharge shall not cause sedimentation or concentrations of any materials in the receiving waters which are deleterious to human, animal, aquatic, or plant life.

6. The discharge shall not cause esthetically undesirable discoloration of the receiving waters.

7. The discharge shall not cause fungus, slimes, or other objectionable growths in the receiving waters.

8. The discharge shall not cause bottom deposits in the receiving waters.

9. The discharge shall not increase the turbidity of the receiving waters by more than 10% over immediately upstream levels.

10. The discharge shall not alter the pH of the receiving water more than 0.5 units from immediately upstream levels.

11. The discharge shall not increase the temperature of the receiving water more than 5°F (3°C) from immediately upstream levels.

12. The discharge shall not cause a violation of any applicable water quality standard for receiving waters adopted by the Board or the State Water Resources Control Board as required by the Federal Water Pollution Control Act and regulations adopted thereunder. If more stringent applicable water quality standards are approved pursuant to Section 303 of the Federal Water Pollution Control Act, or amendments thereto, the Board will revise and modify this Order in accordance with such more stringent standards.

13 This permit shall be modified, or alternatively, revoked and reissued, to comply with any applicable effluent standard or limitation issued or approved under Sections 301(b)(2)(C), and (D), 304(b)(2), and 307(a)(2) of the Clean Water Act, if the effluent standard or limitation so issued or approved:

(a) Contains different conditions or is otherwise more stringent than any effluent limitation in the permit; or

(b) Controls any pollutant not limited in the permit.

The permit as modified or reissued under this paragraph shall also contain any other requirements of the Act then applicable.

D. Provisions:

1. Neither the discharge nor its treatment shall create a nuisance or pollution as defined in Section 13050 of the California Water Code.

2. The settling ponds shall be designed to contain the flow from the 10 year frequency storms in a 24 hour period.

   Annually, prior to the rainy season, the settling ponds shall be inspected and maintained to ensure the design capacity is provided.

3. The Discharger shall comply with all the items of the "Standard Provisions and Reporting Requirements (NPDES)", dated 1 January 1982, which are part of this Order.

4. The Discharger shall comply with the attached Monitoring and Reporting Program No. _____ as ordered by the Executive Officer.

5. This Order expires on 1 August 1988 and the Discharger must file a Report of Waste Discharge in accordance with Title 23, California Administrative Code, not later than 180 days in advance of such date as application for issuance of new waste discharge requirements.

6. In the event of any change in control or ownership of land or waste discharge facilities presently owned or controlled by the Discharger, the Discharger shall notify the succeeding owner or operator of the existence of this Order by letter, a copy of which shall be forwarded to this office.

7. The provisions of this Order are not intended to, and shall not limit or reduce any obligations or requirements which are additional to, or more stringent than, those created pursuant to this Order and which are imposed on the Discharger pursuant to (a) the terms of any agreement to which the Discharger is a party, including but not limited to, that certain agreement dated as of 30 June 1983, by and between the Discharger and the Solano Irrigation District, or (b) the requirements and controls imposed by any governmental agency or other authority having jurisdiction with respect to the Project. Nothing in this paragraph shall be construed to release or excuse the Discharger from full and timely compliance with the requirements of this Order or amendments or supplements hereto.

I, WILLIAM H. CROOKS, Executive Officer, do hereby certify the foregoing is a full, true, and correct copy of an Order adopted by the California Regional Water Quality Control Board, Central Valley Region, on _____.

CALIFORNIA REGIONAL WATER QUALITY CONTROL BOARD
CENTRAL VALLEY REGION

MONITORING AND REPORTING PROGRAM NO. _____

NPDES NO. CA0081477

FOR
McLAUGHLIN MINE
HOMESTAKE MINING COMPANY
AND
US BUREAU OF LAND MANAGEMENT
YOLO, LAKE AND NAPA COUNTIES

Sample stations shall be established such that the samples are representative of the volume and nature of the discharge.

EFFLUENT MONITORING

During each discharge period, the discharge from each settling pond (discharges 001, 002, 003, 004, 005) shall be sampled and analyzed according to the following schedule:

Constituent	Units	Type of Sample	Frequency
Flow	Gallons per day	Estimate	Daily
Temperature	°C	Grab	Daily
TDS	mg/l	Grab	Daily
EC	umhos/cm	Grab	Daily
pH (field)	pH units	Grab	Daily
pH	pH units	Grab	Daily
Suspended Solids	mg/l	Grab	Daily
Settleable Solids	ml/l	Grab	Daily
Total Alkalinity	mg/l	Grab	Daily
Calcium	mg/l	Grab	Daily
Chloride	mg/l	Grab	Daily
Nitrate	mg/l	Grab	Daily
Sulfate	mg/l	Grab	Daily
Ammonia	mg/l	Grab	Daily
Boron	mg/l	Grab	Daily
Arsenic	mg/l	Grab	Daily
Barium	mg/l	Grab	Daily
Beryllium	mg/l	Grab	Daily
Cadmium	mg/l	Grab	Daily
Chromium	mg/l	Grab	Daily
Copper	mg/l	Grab	Daily

Constituent	Units	Type of Sample	Frequency
Iron	mg/l	Grab	Daily
Lead	mg/l	Grab	Daily
Magnesium	mg/l	Grab	Daily
Manganese	mg/l	Grab	Daily
Mercury	mg/l	Grab	Daily
Nickel	mg/l	Grab	Daily
Sodium	mg/l	Grab	Daily
Selenium	mg/l	Grab	Daily
Vanadium	mg/l	Grab	Daily
Zinc	mg/l	Grab	Daily

Metals shall be analyzed and reported as totals.

RECEIVING WATER MONITORING

Receiving water samples shall be collected daily during periods when discharge is occurring. All samples shall be grab samples taken near mid-stream, where safety permits. Samples shall be taken from each sampling station and analyzed for the following constituents:

Station	Description
R-1	Hunting Creek, upstream of tailings disposal pond or at the northern end of the tailings stormwater diversion ditch
R-2 (HC-9)	Hunting Creek, 1/2 mile downstream of tailings dam
R-3 (HC-5)	Hunting Creek, 1/2 mile upstream of Waste Rock Disposal area
R-4 (HC-10)	Hunting Creek, 1/2 mile downstream of Waste Rock Disposal area
R-5 (KC-3)	Knoxville Creek, 1/4 mile west of Knoxville

Constituent	Units
Flow	Gallons per day
Temperature	°C
TDS	mg/l
EC	umhos/cm
pH (field)	pH units
pH	pH units
Suspended Solids	mg/l
Settleable Solids	ml/l

Constituent	Units
Total Alkalinity	mg/l
Calcium	mg/l
Chloride	mg/l
Nitrate	mg/l
Sulfate	mg/l
Ammonia	mg/l
Boron	mg/l
Arsenic	mg/l
Barium	mg/l
Beryllium	mg/l
Cadmium	mg/l
Chromium	mg/l
Copper	mg/l
Iron	mg/l
Lead	mg/l
Magnesium	mg/l
Manganese	mg/l
Mercury	mg/l
Nickel	mg/l
Sodium	mg/l
Selenium	mg/l
Vanadium	mg/l
Zinc	mg/l
Turbidity	NTU

Metals shall be analyzed and reported as totals.

REPORTING

In reporting the monitoring data, the Discharger shall arrange the data in tabular form so that the date, the constituents, and the concentrations are readily discernible. The data shall be summarized in such a manner to illustrate clearly the compliance with waste discharge requirements.

Monthly monitoring reports shall be submitted to the Regional Board by the 15th day of the following month.

If the Discharger monitors any pollutant at the locations designated herein more frequently than is required by this Order, he shall include the results of such monitoring in the calculation and reporting of the values required in the Discharge Monitoring Reporting Form. Such increased frequency shall be indicated on the Discharge Monitoring Reporting Form.

The Discharger shall submit a report to the Board by 30 January of each year containing both tabular and graphical summaries of the monitoring data obtained during the previous year. In addition, the Discharger shall discuss the compliance record and the corrective actions taken or planned which may be needed to bring the discharges into full compliance with the waste discharge requirements.

The Discharger shall implement the above monitoring program on the effective date of this Order.

EXAMPLE OF 1982 CALIFORNIA DISCHARGE SPECIFICATIONS

Board Order No. 6-82-35

I. DISCHARGE SPECIFICATIONS

1. The discharge of wastewater or tailings except to the designated disposal sites is prohibited.

2. The wastewater evaporation pond shall be effectively sealed[a/] to prevent the exfiltration of any liquids from the pond.

3. The disposal of tailings and wastewater shall be in accordance with the plan described in the D'Appolonia report referenced in footnote "a".

4. The use of a flocculant with similar characterisitcs to the type used in the tailings test and reported on in the D'Appolonia report is required to increase the specific retention of the tailings.

5. The "emergency" tailings disposal site shall effectively be sealed[b/] to prevent the exfiltration of any liquids from the site.

6. The discharge of liquids of any type to the tailings disposal site is prohibited except for limited quantities of freshwater for dust control.

7. At no time shall tailings having a moisture content in excess of 32 percent be disposed of at the tailings disposal site.

8. The average[c/] water content of tailings disposed of at the tailings disposal site shall not exceed 30 percent.

9. The disposal of tailings is limited to only those areas of previous tailings disposal where the measured moisture content of the previous lift falls below the "moisture control curve" as shown on Figure 18j in the July 1981 D'Appolonia report.

10. In the event that wastewater is detected in the evaporation pond underdrain system, the February 24, 1982 "System Failure Contingency Plan" shall be implemented.

11. In the event that (1) the measured moisture content within the placed tailings in any moisture detection well exceeds the specifications as defined in Figure 18j (Moisture Control Curve) of the July 1981 D'Appolonia report, or (2) the measured moisture content in the foundation soils increases by more than 4 percent above the background at a depth of five (5) feet (as measured prior to tailings disposal), then the "System Failure Contingency Plan" dated February 24, 1982, shall be implemented and a report as specified in the "Plan" be provided to the Regional Board within four weeks.

a/ As an acceptable minimum, construction of the pond liner shall consist of a 30-mil thick hypalon membrane covered with one foot (0.3 m) of soil as specified in "Tailings Disposal Plan" dated July 1981 and prepared by D'Appolonia Consulting Engineers, Inc.

b/ The emergency tailings disposal site shall be sealed with a 30-mil hypalon liner as specified in the January 26, 1982 "Lined Emergency Disposal Facility Design and Tailings Compaction Specifications", prepared by D'Appolonia Consulting Engineers.

c/ The arithmetic mean of daily water content averages measured during any 30 consecutive-day period.

12. The tailings disposal area shall at all times be sloped to a minimum grade of 0.5 percent to provide adequate drainage and prevent ponding of precipitation.

13. Diversion ditches shall be constructed upgradient of the tailings disposal area and shall be maintained by ASARCO, Inc. both during the project and following its completion as specified in the D'Appolonia report.

14. Collection ditches to collect surface runoff from the tailings disposal area shall be constructed and shall be maintained by ASARCO, Inc. both during the project and continuously following its completion as specified in the D'Appolonia report.

15. There shall be no discharge, bypass or diversion of tailings or wastewater from the collection, transport, or disposal facilities to adjacent land areas.

16. There shall be no surface flow or visible discharge of wastewater or tailings from the designated disposal sites to adjacent land areas.

17. All facilities used for collection, transport, or disposal of waste shall be adequately protected against damage resulting from overflow, washout or inundation from a storm or flood having a recurrence interval of once in 100 years.

18. The vertical distance between the water surface elevation and the lowest point of a pond dike or the invert of an overflow structure shall not be less than 1.5 feet (0.46 m).

19. The discharge shall not cause a pollution or a nuisance.

II. PROVISIONS

1. Site closure and maintenance shall be implemented in accordance with the discussion of "Abandonment/Reclamation" in the D'Appolonia report and as described further in a December 1, 1981 letter from ASARCO, Inc. to the Regional Board.

2. The discharge shall comply with Monitoring and Reporting Program No. 82-35 as specified by the Executive Officer.

3. The discharger shall immediately notify the Regional Board by telephone whenever there are any accidental spills of wastes containing cyanide or any other toxic materials on the subject property, or when any other adverse condition occurs as a result of this discharge; written confirmation shall follow.

4. Any proposed material change in the character of the waste, manner or method of treatment or disposal, increase of discharge, or location of discharge shall be reported to this Regional Board at least ninety (90) days in advance of implementation of any such proposal.

CANADA

In Canada, generally, precipitation exceeds evaporation and, ultimately, the discharge of an effluent from a tailings impoundment cannot be avoided using conventional tailings disposal techniques.

Canada's water quality protection laws fall under their Fisheries Act because effluents find their way into the huge lake and river system of Canada which supports major fishing and recreaton industries related to fishing.

As in the U.S.A., Canadian regulations are established on a federal level based on recommendations by Environment Canada, Environment Protection Service. Each province has its own Ministry of the Environment. In the case of some of these, e.g., British Columbia, environment protection, including mine-mill effluents, are regulated by the province. In the case of others, e.g., Ontario, the province maintains a strong advisory service and, although it is empowered to issue directives which can shut an operation down or force it to rectify a problem, the regulation and permitting of mines and mills is left to Environment Canada.

Although in Canada the regulators have and do exert their powers to close down operations if regulations are not adhered to, the impression gained is that regulators are much more conscious of the role of mining in their national and local economies. There appears to be a greater awareness amongst regulators of the need to preserve employment. Also, Environment Canada studies numerous site-specific cases to determine their needs and, working with industry, will test and promote the development of improved technologies to solve environmental problems in real life situations.

Environment Canada first goes out to define a problem, in several cases representing the range of industry-wide conditions. It then finds out, based on real field tests, what can be done to solve the problem and what it will cost. Then finally, it proposes regulations which oblige industry to solve the problem using the practical solutions it has demonstrated.

This contrasts with the EPA and states in the U.S.A. which have been known to regulate a problem by dictating what results must be achieved before a practical solution is available or known.

RANDOL INTERNATIONAL LTD., in the course of this investigation, found the Canadian federal and provincial authorities much more accessible, more helpful, and generally better informed about the environment protection problems and the nature and needs of the mining industry. They were also more problem solving-oriented than in the U.S.A. where the regulators seem to concentrate on the problems and regulations rather than

finding and suggesting practical answers. In short, the Canadian system appears to be more service oriented as reflected in the name, Environment Protection Service.

In Canada, regulation of uranium mines and mills falls under the Atomic Energy Control Board although provincial ministries of the environment have the right to issue control orders if they find the AECB measures inadequate in specific instances.

In Canada, details of regulations governing effluents would be available on request from the Federal Environment Protection Services, Environment Canada, and from each province as to their provincial regulations:

SOUTH AFRICA

The South African government in a rare and commendable example of resisting an opportunity to create yet another bureaucracy; intelligently combined environment protection into the Dept. of Water Affairs and changed its name to the Dept. of the Environment. Environment protection and water resource management and protection are, after all, synonymous. The change in name, however, reflects the emphasis that the South African government has decided to place on water resource protection.

Apart from a change in the environment protection regulations affecting water quality, there has been a recent beefing up in enforcement of the existing regulations and a general tightening in these interpretation. For example, in February, 1984, the Dept. of the Environment was advertising for 15 new water inspection professionals with experience in the mining industry.

The Water Research Commission, a state funded organization, has sponsored several major studies on the future needs of water for growth projected in the South African economy. It also surveyed the impact of point source mine effluents on the quality of water in the Vaal Dam which serves as the main regional water supply to the industrial heart of the country, and further research into the impact of diffuse source effluents, e.g., runoff

and seepage from slimes and sand dumps created by gold and uranium mining and milling operations.

The National Institute for Water Research of the CSIR is yet another state funded research organization whose mandate is to develop improved technology for water treatment.

The Dept. of the Environment is the permitting and policing agency for all major water users and dischargers of effluents.

Most of the South African metal mining areas experience net evaporation climates, and metallurgical operations and tailings can be designed for zero discharge if necessary. Minewater is pumped to the surface in very large quantities--far too large to be wasted in a water deficient country.

One of the main indicated new directions of the Dept. of the Environment's proposed changes to regulations is clearly the prevention of TDS buildup in Vaal Dam water and in promotion of water conservation measures within industry. Since mining and metallurgical operations are major users and dischargers of water containing high TDS, the implementation of the new regulations can be expected to be focused on this industry.

In South Africa, uranium is recovered from the same ore as gold; therefore due to practical considerations, the environmental aspects of both are regulated by the Dept. of the Environment. The Atomic Energy Board does not get involved in mine/mill tailings management or effluent treatment and discharge.

The South African government will never let the Dept. of the Environment stifle the mining industry on which the whole country's economy relies, but there will be much tougher and more expensive rules to live within.

SOUTH AFRICAN REGULATIONS

Regulations concerning water discharge by mines are contained in "Effluent Standards promulgated in terms of Section 21 of the Water Act, Act 54, 1956, as amended. Various additional amendments include those published in the Government Gazette:

R1029, 18 June, 1976:
On sewage effluent measurement and reporting of water analyses from mines.

R287, 20 February, 1976:
Control measures for control of surface water showing existing and planned minerals, tailings, wasterock dumps, and slimes dams for the following five years.

Para 6.1: The manager of a mine or works shall, unless otherwise authorized in writing by the Secretary, prevent the pollution of any water, cause effective measures to be taken to prevent effluent, including water pumped from underground or which flows naturally from a mine or works, to flow or seep beyond the boundaries of the property on which the mine or works is situated.

Para 7: The manager of a mine or works shall make adequate provision to the satisfaction of the Secretary to prevent as far as reasonably practicable runoff from eroding slimes dams and mineral tailings and wasterock dumps due to rain.

Para 8: All runoff due to rainfall on a property on which a mine or works is situated must be controlled in such a manner by a system of storm water dams that it flows clear of slimes dams, mineral tailings, or wasterock dumps and other sources of pollution. Provision shall be made for the maximum precipitation expected over 24 hours on a 100-year frequency. A freeboard of at least 0.5 m shall be provided throughout the system above the expected maximum water levels.

Para 9: All waterways on a property on which a mine or works is situated shall be fenced in and protected to prevent pollution of any water.

Para 10: Prevention of any extraneous liquid or other material from entering any evaporation dam, storm water drain, or other entering the evaporation dam, storm water drain, etc.

Para 11.1: All slimesdams, mineral, tailings, and wasterock dumps to be so designed and constructed or modified that all rainwater precipitated thereon is retained thereon. Barrier dams and evaporation dams shall be provided to collect any runoff. Storage capacities shall provide at least 0.5 m freeboard above water level based on average monthly figures over 24 hours (100-year flood).

Para 11.2: Rainwater from tailings dumps and the appurtenat barrier dams and water used in any process at a mine or works shall be recycled wherever possible.

Para 11.3: Trench drains and ditches to catch seepage water and carry it to evaporation dams or sumps for recycling shall be constructed at all tailings dumps whenever possible.

Para 11.4: All pumps and pumping installations, including catchment dams for the recycling of water shall be of a design and of adequate capacity to prevent the uncontrolled release of water at any time.

Para 12: Mining, tailings, wasterock dumps and any slimes barriers or evaporations dams, waterways, etc. shall be designed to minimize the possibility of damage thereto due to past, present, or future operations at the mine works.

Para 13: Maintenance by the mine manager of the dam wall of storm-water drains and other waterways.

Para 14: "Best practicable means" as determined by the Secretary shall be implemented to prevent erosion of material from the sides of tailings dumps and slimes dams.

Para 15: Collection and evaporation of seepage from outcrops or sub-outcrops occurring on a property on which a mine or works is situated and which does not conform to the standard prescribed in terms of Section 21(1)(a) of the Act.

Para 16.1: Siting of mineral, tailings, or wasterock dump, slimes dam, evaoration dam, or any other dam or furrow containing polluted water shall not be near any spring or with 45 meters from 50-year flood waterline of any river or watercourse.

Para 16.2: No mineral, tailings, or wasterock dump or slimes dams or evaporation dams to be sited on waterlogged ground or ground likely to become waterlogged.

Comprehensive regulations regarding most aspects of water in and around mines and mills.

Regulations are in place. Change in the degree of strictness with which they are enforced makes a big difference.

R553, 5 April, 1962, Regional Standards for Industrial Effluents which include Mines: Regulatory standards for any waste water or effluent produced by or resulting from the use of water for industrial purposes in catchment areas draining to the rivers or portions of rivers. Summary:

Special Standard: Stricter than the General Standard and Special Standards apply to only certain specific rivers or sections of rivers where trout exist. These are listed in the previous chapter in addition to the proposed new standard applicable to the PWVS Region (Vaal Dam Drainage).

New Regulations and Changes Pending

The Water Act itself is under a broad review in Parliament. There are several changes under consideration as well as some new regulations.

1. New regulation proposed to set new standards for heavy metals, lead, chromium, mercury, and cadmium. The standard proposed has not yet been finalized to a degree that is firm enough to be reported on.

2. Proposed new regulation which would limit TDS of effluent streams to 250

milliSiemens/m. This is the equivalent to around 2,000 ppm TDS and would mean that the mining industry would have to evaporate more effluents or install desalination plants. Government Notice R1567, 1 August, 1980.

3. Standard limiting $PO_4^{=}$ as soluble orthophosphates to 1 ppm max. in certain catchments from 1 August, 1985, i.e., Vaal River upstream and including Bloemhof Dam, Pienaars River and Crocodile River upstream of their confluence, Great Olifants River upstream and including the Loskop Dam, The Umgeni River, Umlaas River, Buffalo River to Bridle Rift Dam, and the Berg River.

4. Regulations R287 of 20 February, 1976, pertaining to the Water Act are currently under review. This review is in its initial stages.

5. New mine plans must now be submitted to the Government Mining Engineer who consults the Dept. of the Environment. The plan must include restoration on completion of operations. Restoration factors are critical with respect to water aspects.

Conclusions - South Africa

1. Water use by the mining and metallurgical industry and discharge of effluents by mines and mills will come under increasing scrutiny in South Africa. This is quite evident in the statements of Mr. Hendrik J. Best, Director of Water Pollution Control of the Dept. of the Environment in the SA Mining & Engineering Journal 1984 inserted below.

2. The mining industry contributes 12% of the volume of water draining into the Vaal River but contributes 30% of the TDS. Mine effluents are point sources which are easy to identify.

3. Water cost to the mining/metallurgical industry will go up. Costs include purchase, pumping, and disposal.

4. New regulations will be much sricter toward the mining industry, and existing regulations will be more strictly enforced. Before a new mine can start up, its plans will be scrutinized. New methods of analysis and new water treatment technology is becoming available which the enforcement officials should be implemented.

5. Needed: Guideline document on how a closing down mine should be restored for abandonment.

6. When a mine has been passed for abandonment, it becomes the responsibility of the SA Dept. of the Environment.

7. Dept. of Environment and Water Research Commission seem to be heading toward encouraging the use of desalination for mine/mill effluent treatment. A SRK study showed that evaporation is probably cheaper. Conclusion: More evaporation dams will be needed.

8. Apparently so far, the South African regulators have focused minimal attention on groundwater quality and monitoring.

Implications of amendments to the Water Act

No pool or stream is sacrosanct when people seek to dump unwanted junk or even poisonous chemicals. The amendments to the Water Act, however seek to remedy this.

The far-reaching implications of the amendments to the Water Act (Act 54 of 1965) — regarding the use of water and measures imposed to prevent pollution — have been detailed for SA Mining and Engineering Journal by Mr H I Best, Director of Water Pollution Control of the Department of Environment Affairs.

Mr Best outlined the consequences of the amended legislation particularly in so far as the use of water by industry and mining is concerned and the steps laid down for the disposal of effluent.

He outlined the following sections of the Act, with the reasons for their amendment.

Section 12:

Before amendment the Act required any person intending the use of water for industrial purposes, or to expand such use, to inform the Department of Water Affairs beforehand of his proposed method of purification of effluent and, if the quantity of public water to be used exceeded 300 m³ on any one day, or an average of 250 m³ per day during any month, to obtain from the Minister a permit authorising such use.

In terms of the amended Act no person may use more than 150 m³ of any water on any day for industrial purposes (as defined in Section 1), whether private or public water, or underground water, or sea water brought ashore, without a permit, irrespective or whether or not any waste water is returned to any public stream. However, any person who at the date of the amending legislation lawfully used more than 150 m³ of water a day is entitled to a permit, subject to such conditions as the Minister may deem fit to impose.

Appliction forms for permits are obtainable from the head office and all regional offices of the Department.

Section 12A:

This section is an addition to the Act and places a prohibition on the construction or enlargement of any water work used for the purification, treatment or disposal of effluent, including sewage.

Regulations are to be promulgated shortly describing the minimum number of personnel with their minimum qualifications, to be employed for the operation of the various classes of water care works. Before promulgation the draft regulations will be published in the Government Gazette to give the public an opportunity of commenting on them.

Section 20:

In this section the alteration to the course of a public stream is prohibited, unless authorised by permit, mainly to regularise river deviations for the purposes of open-cast coal mining. These provisions do not affect the activities of a local authority within its area of jurisdiction or the construction of a soil conservation work in terms of the Conservation of Agricultural Resources Act, 1983.

This picture tells its own story.

Section 21:

This section deals with the purification, treatment and disposal of effluent occasioned by the use of water for industrial purposes. The amendments do not deviate materially from original objectives, except that —

- previously any industry discharging its effluent into the sewer of a local authority concerned was responsible for such compliance. Now, however, the Minister may direct that any particular industry shall not be so exempted, and each case will be treated on its own merits and
- any effluent discharged into a canal, sewer or other conduit controlled by a local authority, body or person having authority to undertake the purification, treatment or disposal of effluent, is deemed to be effluent produced by or resulting from the use of water by that local authority, body or person for industrial purposes. This means that a local authority will henceforth be responsible for the purification, treatment and disposal in accordance with the provisions of Section 21 of the Act, of any effluent released with or without its consent or knowledge into a stormwater drainage system under its control.

Section 22:

This is a new provision. Subsection (1) states:

"Any person who has control over land on which anything was or is done which involves a substance capable of causing water pollution, whether such substance is a solid, liquid, vapour or gas or a combination thereof, shall take such steps as may be prescribed by regulation under Section 26 in order to prevent:

- any public or private water on or under that land, including rainwater which falls on or flows over or penetrates such land, from being polluted by that substance, or if that water has already been polluted, from being further polluted by that substance; and
- any public or private water on or under any other land, or sea, from being polluted, or if that water has already been polluted, from being further polluted, by water referred to in the previous paragraph, which became polluted in the circumstances described."

Regulations will be framed shortly to compel industrialists to take the precaustions outlined above.

Section 24:

This is also a new section, which vests in the Minister and the Director-General certain powers to prevent water pollution before it can take place.

The Director-General may authorise any person to enter upon any land referred to in Section 22 (1) or on which water is used for industrial purposes or on which effluent is disposed of and to conduct on such land such investigation as the Director-General may determine (It should be mentioned that such authority is subject to a prohibition, in terms of Section 166A of the Act, on the disclosure of information gained during the investigation).

If the Director-General, as a result of such investigation, is of the opinion that any steps carried out on such land to prevent water pollution are in the particular circumstances inadequate or ineffective, he may direct the person responsible for carrying out those steps to take such additional or other steps as are deemed necessary for the prevention of water pollution. Any person aggrieved by such direction may appeal to the Minister.

If a person fails to comply with such direction within a period specified, the Minister may isntruct the steps to be carried out and recover the cost incurred from the person to whom the direction was issued.

In terms of this Section the Mininster may by notice in the Government Gazette direct that the manufacture, marketing or use of any substance which, in his opinion could cause water pollution, be terminated or restricted, or he may subject the manufacture, marketing or use thereof to the conditions specified in such notice.

If a person:

- uses water for industrial purposes contary to the provisions of Section 12;
- fails to comply with any provision of 21 (1) or 22 (1); or
- fails to comply with an direction issued to him under Section 24; the Minister may direct that the supply of water to such person for industrial purposes, whether from a Government water works or any other water works, be suspended or reduced. In such event the State, the Minister or any person carrying out such direction is not responsible for any loss or damage caused thereby.

Section 30:

Before the amendment to the Act the owner of a mine was entitled to remove from the mining area any water found underground if such removal was necessary for mining operations or the safety of his employees and, unless the Minister otherwise directs, to use such water for mining operations. In terms of the amending legislation such use is subject to the provisions of Sections 12 and 21. Therefore the mine owner may not use such water unless he is authorised to do so under permit (if the quantity exceeds 150 m^3 on any day) and he is obliged to treat any effluent resulting from such use in accordance with the provisions of Section 21.

Section 41:

In terms of the amendment a mine owne: will henceforth be entitled to claim a servitude under the Water Act for the purposes of disposing of water found underground and removed from the mining area.

Section 170:

The penalties prescribed for offences under the Water Act have been enhanced considerably in the amending legislation. As far as water pollution is concerned the maximum penalty for a first offence is increased from R2 000 to R10 000 and for a subsequent offence from a minimum of R1 000 to a maximum of R20 000. Alternative imprisonment is increased from six to 12 months. In the case of a continuing offence the penalty is increased from R100 to R200 in respect of every day the offence continues.

An addition to the Act reads as follows:

"Whenever any person is convicted of an offence under this Act, the court convicting him may summarily enquire into and assess the monetary

Severe penalties are contained in the amended Act for offences regarding use of water and pollution.

value of any advantage gained by such person in consequence of that offence and, in addition to any punishment imposed in respect of that offence, impose on that person a fine equal to the amount so assessed or, in default of payment, imprisonment for a period not exceeding one year."

Section 171:

Although there are only slight amendments to this section, mention is made thereof in view of its implications. Whenever any person is convicted of an offence under the Water Act and it appears that such person has thereby caused a loss or damage to any other person, the court may, at the request of the said other person determine the amount of the loss or damage and order the conviced person to compensate the person who has suffered loss or damage, in addition to any punishment imposed in respect of the offence.

BRAZIL

Brazil has a Federal Environmental Protection Agency. Each state has its own environmental agency with specific legislation on effluent discharge limits.

The permitting process in Brazil includes three main steps requiring licensing authority approval for all of them.

1. Preliminary license based on general aspects about process units and proposed environmental control measures. An environmental impact assessment may be required, depending on the plant location, capacity, raw materials to be processed, products, and by-products, etc.

2. Installation license based on environmental control systems and basic design of effluent treatment equipment.

3. Operating license based on plant inspection and effluent monitoring.

The licensing agency addresses for three main mining states, and the federal agency are shown below. The federal agency can provide complete detailed information.

1. Federal Agency:

SECRETARIA ESPECIAL DO MEIA AMBIENTE

4. Minas Gerais:

COMISSAO DE POLITICA AMBIENTAL
Rua da Bahia, 916 - and Andar
30.000 Belo Horizonte MG
Telephone: (031) 1775

There is no specific legislation on environmental control for mines and mills. U.S. EPA criteria are often used as guidelines or for contaminant levels in permits. State liquid effluent discharge limits must be met for mine drainage, rainwater runoff, and process effluents. A guiding rule is that ground water must be protected against infiltration by contaminated wastes.

Mine area reclamation is required as well as "proper" transportation and disposal of solid wastes.

Effluent discharge limits for some contaminants as laid down by three Brazilian states are as follows:

Parameter	Unit	Rio	S. Paulo	Minas Gerais
pH	-	5-9	5-9	6-9
Sedim. Solids	ML/L	1.0	1.0	1.0
DB05	MG/L	(*)	60	60
Cyanide	MG/L	0.2	0.2	0.2
Arsenic	MG/L	0.1	0.2	0.2
Copper	MG/L	0.5	1.0	0.5
Lead	MG/L	0.5	0.5	0.1
Zinc	MG/L	1.0	5.0	1.0
Nickel	MG/L	1.0	2.0	1.0
Mercury	MG/L	0.01	0.01	0.01
Cadmium	MG/L	0.1	0.2	0.1
Chromium III	MG/L	1.0	5.0	1.0
Chromium VI	MG/L	1.5	0.1	ND
Fluorides	MG/L	10	10	10
Sulfides	MG/L	1.0	-	0.5
Oil and Grease	MG/L	20	100	20
Temperature Degc.		40	40	40

* Depending on receiving water quality in terms of flowrate, flowpattern, and dissolved oxygen.

Note: Priority pollutants such as carcinogens are submitted to specific legislation.

CHILE

In Chile, the Ministry of Mines approval must be granted for all mine-mill projects.

The National Health Service approval is needed for tailings disposal plans as they affect water quality protection.

The Ministry of Mines approval is required of tailings disposal plans with respect to their safety.

Effluent limitations are not prescribed in Chile.

RANDOL is indebted to Utah International, Inc. for providing the following copy of relevant Chilean regulations governing mine-mill wastes.

(106) DECREE NUMBER 86 of JULY 31, 1970

APPROVES THE REGULATIONS FOR THE CONSTRUCTION AND OPERATION OF TAILING PONDS

(Published in the Official Record Num. 27,722 of Aug. 13, 1970)

(Considering the need to specify more exactly the concepts and technological demands for the construction of tailing ponds the following decree is issued.)

(107) TITLE I

BASIC DEFINITIONS

Article 1 (Director = Director of Service of Mines

Relave = Suspension of solids in liquids which are thrown out in plants of humid concentration of pure and waste minerals which have gone through one or several stages in fine milling. The word will also be applied to the solid fraction of the pulp which has been described in the suspension mentioned above.

Article 2 Tranque de relave (tailing pond) means the layout for the storage of the tailings which fills the function of locating the solid fraction in a stable structure, and arranging, at the same time, for the partial suspension of solids in liquids and for a liquid fraction, capable of being maintained in safe conditions in respect to possible overflows and other disturbances.

Article 3 The area of the tailing pond in which the finest solid grains will accumulate -by the process of sedimentation- shall be called the muddy (slimy) accumulation.

Article 4 The area of the tailing pond in which the larger solid grains shall accumulate will receive the name sandy accumulation.

Article 5 The area of the tailing pond where muddy accumulation takes place and where the gradual process of sedimentation allows the accumulation of clear water on the surface shall be called the sedimentation pool.

Article 6 The peripheral area of the tailing pond constructed artificially, which complements the natural perimeter to shape inside it the tailing pond and, at the same time, part or all of the sandy area of the pond will be called the resistent prism (Spanish=prisma resistente).

Article 7 The device set up for the collection of clear water from the tailing pond, which is obtained from the sedimentation pool and/or for the collection of water which extrudes from the tailing pond as it solidifies as the water which fills the inergranule spaces is eliminated, will be called the drainage system.

Article 8 The elements set up for the purpose of placing the complete tailings and/or its muddy and sandy components, under conditions of executing an hydraulic fill, will be called the distribution system.

TECHNICAL DEFINITIONS PARAGRAPH II

Article 9 The condition of moisture content in which the granules are resting upon one another, the spaces are completely filled with liquid will be defined as a state of total saturation.

Article 10 Ground water level is the height above sea level at which poihts the molecule water has a pressure equal to zero.

Article 11 The device which measures the ground water level shall be called a piezometer.

Article 12 The constant which determines the permeability of a soil or of any area of the tailing pond, by the expression : $k = v/i$, in which v is the velocity of discharge of water through the soil, and i is the hydraulic gradient is called the "coefficient of permeability".

Article 13 The quantitative description of the distribution of the
(108) sizes of the solid components of the tailings, in reference either to the complete tailings or to a prior separation into a sandy fraction and a muddy fraction, will be called the granulometry of the tailings.

Article 14 (Defines density of tailings)

Article 15 (Defines compaction of the tailings)

Article 16 (Defines density <u>in situ</u>)

Article 17 (Formulae for degree of compaction.)

Article 18 (Formula for resistance capacity to fatigue.)

Article 19 (Measurement of resistance to penetration.) Resistance is expressed as the number of blows of a 65 kilo hammer falling freely from a height of .75 meters required to sink the tube 0.30 meters deep, the indicated sampler having an external diameter of 0.05 meters and its cutting points 60°.

Article 20 (Defines slope angle of supporting prism.)

(109) Article 21 and 22 (Define certain reference lines.)

TITLE II

GENERAL PROVISIONS

Article 23 (State Mining Service has overseeing responsibilities for all projected and operating tailing ponds.)

Article 24 (State Mining Service also has responsibility for assuring that users follow all rules for Industrial Safety.)

Article 25 (User of tailing pond responsibility for all consequences resulting from bad use of tailing ponds.)

Article 26 (The user of the tailing pond shall have preferential treatment vis a vis a third party who later want to build structures at the foot of the tailing pond.)

TITLE III

MAINTENANCE AND OPERATION

Article 27 (Information which the user must report periodically to the Service;

a) Details of monthly maintenance work

b) Details of monthly operation

c) Relative density at 1/3 and 2/3 depth at the extreme slope of the resistent prism, with no less than one determination for each 100 meters of length of the prism.

d) Granulometry over 48, 60, 100 and 150 Tyler mesh and under 150 Tyler mesh in percentage, once per month.

e) Subtotals of sands and muds in aggregate tons for the month, for the year and the total since the beginning of the work.

Article 28 (In certain cases specified by the Director user may operate under one of the following: out water system
(110) or mixed system)

Article 29 The sands will be emptied towards the exterior of the pond and above the level of the outside slope, spreading them in such a way that they are spread uniformly, and, in certain cases, compacting in layers no thicker than 30 cm., under moist conditions when possible, to obtain a Proctor percentage equal to or above the limit set by the Director.

Article 30 (The mud will be emptied toward the surface of the mud zone. Other requirements that no water may run into pond. And special cases where the tailings may completely be spread on the sandy and muddy areas.)

Article 31 (Sedimentation pool to be kept clear.)

Article 32 (Measures may be taken by director to maintain freatic level within limits set.)

TITLE IV

EMERGENCY TASKS

Article 33 (User must pay for emergency measures required by Service.)

Article 34 (Service may adopt following means:

a. Rupture of lower drainage system, resulting in mixture of mud with clear water, loose or sacked stone will be dropped at the outlet until problem is corrected;

(111) b. Rupture of distribution system, plant shut down until fixed.

c. Heavy snow causing ice on slopes may necessitate stoppage of sand spreading or temporary work stoppage.

d. Earthquakes causing structural damage will cause suspension of use.

TITLE V

DESIGN AND OPERATION STANDARDS

Article 35 (Tailing ponds to be designed in accordance with the principles of Soil Mechanics and Foundation Engineering.)

Article 36 Waters which run permanently, temporarily or accidentally will be deflected to assure fulfilment of Article 30. Therefore the design will include necessary civil works and the justification for their dimensions.

Article 37 (Requirement to achieve an increase in the permeability of the soil to meet Article 32.)

(112) Article 38 (Definition and formula for a safety factor.)

Article 39 (Drainage of resistent mass)

Article 40 (What information must appear in the request to construct a tailing pond.)

(113) Article 41 (Director will set periodic information.)

Article 42 (Director will set relative density factor.)

Article 43 (User will furnish information on all auxiliary works.)

TITLE VI
SCOPE OF APPLICATION

Article 44 (Present regulation applicable to tailing ponds under construction and those already operating which have populated areas below them.)

Article 45 (Formula for determining danger distance.)

Article 46 (The Director may reduce the requirements or establish exceptions under the following conditions.

a) Length of supporting prism is less or a most equal to 0.2 of the perimeter of the pond;

b) (Sandy fraction and/or constituents of the frontal prism represent together 150% of the muddy fraction.)

c) (Sedimentation to be developed in rotational manner thus limiting tonnage in face of possible liquification.)

d) (a) or b) above require achieving revetment of 6 meters and or berm above or equal to 15 meters.)

e) (In areas with less than 500 mm of annual precipitation and with a maximum of no more than 50mm. of rain in 24 hours, the vertical development of the pond will be less then or at the most equal to 1/2 cm. per day.)

Article 47 (Users who will undertake to construct tailing ponds under articles 44 to 47 must have preliminary, provisional approval of plans by the Director, and later meet requirements of Article 40.)

Article 48 (Users have 6 months to conform.)

Article 49 (Director has the authority to change procedures herein as the science of soil mechanics developes.)

TITLE VII

SANCTIONS

Article 50 (Reference to Decree 32, Article 316 for sanctions)

(023) Article 30. In no case can industrial or mine tailings, or water contaminated with toxic products, be put into the ground water system, irrigation canals, aquaducts, rivers, swamps, streams, lakes, lagoons, reservoirs, general water flows or masses, unless they have first been purified or neutralized by treatment prescribed, in each case, by the National Health Service.

Article 31. In no case can solid materials, which may come from industrial establishments or general work areas, or seeds harmful to agriculture, be discharged into general water courses or masses.

Article 32. The final elimination and disposition of waste and resulting residual products, be they organic or inorganic, solid or liquid, putrescible or not, from diverse industrial processes, that are not eliminated through the culvert system, must be carried out in the form and under the conditions determined by existing Regulations or, in special cases assessed by the National Health Service, in a way determined by that same agency.

Dust, garbage, trimmings, and waste in general, will be regularly removed in such a way as to avoid any bother or inconvenience to the industry personnel and the neighborhood. Where harmful or toxic solid products are handled, sweeping should be done outside of working hours by personnel with adequate protection.

SWEDEN

All mines and mills in Sweden require a permit. The licensing authority is the Water Court and/or the Franchise Board.

The permit regulates, for example, the maximum annual ore production rate and, in some cases, the maximum amount of discharge permitted under special conditions.

No fixed limits on contaminants are set but are decided upon cases by case, based on site specific aspects.

BOLIDEN MINERAL A/B operations are still in an investigation stage to determine what effluent limits will be set. To date, very few limits have been set.

pH at two of BOLIDEN's dailings dam effluents has been set at 7.0 and 8.0 respectively. There are guidelines for maximum allowable concentrations of Cu, Pb, Zn, Cd, As, Hg, Cr, and CN. Regulated maximum contaminant levels have been laid down only in exceptional cases.

The limit for suspended solids is 10 mg/l in the one case where it is regulated. In one regulated case, the combined Cu, Pb, Zn, Cd, As, and Hg monthly average is maximum 1 mg/l.

In one case, a limit guideline for chromium has been set at 0.1 mg/l (monthly average). A free cyanide level of max. 0.5 mg/l has been set from July, 1986, and the target level is 0.2 mg/l for one of BOLIDEN's operations.

The address of the Franchise Board is:

KONCESSIONSNAMNDEN FOR MILJOSKYDD
Box 34067
S-100 26 Stockholm
Sweden

There are several Water Courts. One of them in the county of Stockholm has the following address:

STOCKHOMS TINGSRATT
Vattendomstolen
Box 510
S-10126 Stockholm
Sweden

RANDOL INTERNATIONAL is indebted to Torbjorn G. Ransson of BOLIDEN for the above summary.

For presentation at the AIME Annual Meeting
Dallas, Texas - February 14-22, 1982

Abstract. Hydrometallurgical processes are not free of environmental regulations. A clear understanding of the regulations under which the minerals industry operates delineates processing requirements at early stages. This paper deals with federal environmental regulations with emphasis on the hazardous waste regulations promulgated in May, 1980. The procedure of EP toxicity test and an example of the test are described. Brief account is given of the current trend and future outlook of regulations.

Introduction

Profound changes have taken place and more are expected in the minerals industry due to the emergence of environmental awareness both in the general population and elected representatives. Ambient air regulations on sulfur dioxide have been major contributors to the trend away from the traditional pyrometallurgical processes which is evident now. Additional motivation has been furnished by the Occupational Safety and Health Administration (OSHA) in the case of some metals, like lead and zinc. Hydrometallurgical processes have been regarded as the means of circumventing these environmental problems. However, hydrometallurgical processes themselves are not free of regulation which is the subject of this paper.

The technical feasibility by which existing and emerging processes are measured includes their environmental acceptability as a large component. Such concerns have major effects on process economics and viability. A clear understanding of the regulations under which the minerals industry operates would facilitate the technical tasks by delineating processing requirements at early stages.

This paper is designed to present a brief overview of the Federal environmental regulations relevant to hydrometallurgical process residues as promulgated by EPA. It does not include local or State requirements or others that could by derived, for example, from OSHA regulations. Brief descriptions are included of those approaches the EPA is following in applying the existing regulations to the mineral industries and in promulgating new ones in the future. At the present time, the subject is complex and in a state of flux with major uncertainties derived from the newly promulgated hazardous waste regulations.

General Description of the Regulations

Regulations concerning the protection of the environment are codified under the Title 40 of the Code of Federal Regulations (CFR)(1). Title 40 consists of seven volumes covering regulations on air pollution to procedures for certification of low-emission vehicles. Only those regulations which apply to the mineral industries are included as follows.

Solid Wastes

Parts 240 to 243 of title 40 give guidelines for the thermal processing, the storage and collection of solid wastes. These regulations do not apply to hazardous and mining wastes.

Hazardous Wastes

Parts 260 to 265, which were published recently in the Federal Register(2), are the new hazardous waste regulations. The new Federal "cradle-to-grave" waste monitoring system was effective beginning November, 1980. Since these regulations are of interest to the minerals industries, they will be reviewed in more detail.

The definition of solid waste is given in Section 261.2. A solid waste is any garbage, refuse, sludge, or other waste material, which is not excluded under Section 261.4(a).

Section 261.4 lists special cases which are excluded from the regulations (e.g., mining overburden returned to the mine site). Wastes from processing of ores are not included in these special cases.

Section 261.3 defines what a hazardous waste is. A solid waste is a hazardous waste if:

1) It is not excluded from the regulation as a hazardous waste under Section 261.4(b).
2) It is listed as a hazardous waste in Subpart D of Part 261 and has not been excluded from the lists under Sections 260.20 and 260.22.
3) It is a mixture of solid waste and one or more hazardous wastes listed in Subpart D of Part 261.
4) It exhibits any of the characteristics of hazardous waste identified in Subpart C of Part 261.

Sections 260.20 and 260.22 describe general requirements regarding petitions to modify or revoke any provisions in Part 260 through Part 265 or to amend Part 261 to exclude a waste produced at a particular facility.

Section 261.5 states special requirements for hazardous wastes generated by small quantity generators. If a person generates in a calendar month a total of less than 1000 kg of hazardous wastes, those wastes are not subject to the regulation. Later, EPA revised this paragraph replacing "person" with "generator" (3).

Section 261.6 describes special requirements for hazardous wastes which are recycled. If a hazardous waste is recycled or reclaimed, it is not subject to these regulations.

Subpart C of Part 261 states four characteristics of hazardous waste: ignitability, corrosivity, reactivity, and toxicity.

Section 261.24 describes the characteristics of "Extraction Procedure (EP) toxicity". A solid waste exhibits characteristics of EP toxicity if, using the test method described in the Appendix II of Part 261, the extract from a representative sample of the waste contains any of the contaminants listed in Table 1 at a concentration equal to or greater than the respective value given in that table.

Hazardous wastes from nonspecific sources are listed in Section 261.31 (e.g., spent cyanide bath solutions from metals recovery operations).

Section 261.32 lists hazardous wastes from specific sources (e.g., electrolytic anode slimes/sludges from primary zinc production).

Listed in Section 261.33 are the generic names of commercial chemical product which are hazardous if discarded (e.g., arsenic trioxide).

Appendix II of Part 261 describes the EP toxicity test which can be briefly summarized as follows:

A representative sample is first obtained using the methods specified in Appendix I of Part 261. The sample is separated into its liquid and solid phases. After preparing the solid material for extraction, it is placed in an extractor with 16 times its weight of deionized water. The pH of the solution is continuously adjusted to 5.0 during the 24 hour extraction period. After extraction, deionized water is added, and the material is separated into liquid and solid phases. The liquid is combined with the liquid obtained previously and is analyzed for the presence of any contaminants specified in Table 1 using the analytical procedures designated in Appendix III of Part 261. The separation procedures are described in Appendix II.

Parts 264 and 265 describe standards applicable to owners and operators of hazardous waste treatment, storage, and disposal facilities.

The regulations under Part 265 establish requirements applicable during the interim status period (the period after an owner or operator has applied for a permit, but prior to final disposition of the application) for existing facilities.

These interim regulations require a ground water monitoring system for any surface impoundment, landfill, or land treatment facility which is used to manage hazardous wastes. The owner or operator of a facility has to establish the background ground-water quality of the underlying aquifer. The owner or operator has to determine the concentration or value of the parameters characterizing the suitability of the ground-water as a drinking water supply. Also, the owner or operator has to determine the parameters establishing the ground water quality such as chloride, iron, etc. and the parameters used as indicators of ground-water contamination such as pH, the amount of total organic carbon, etc. Table 2 shows the EPA drinking water standards to be adhered to during the interim status period. Sections 265.90-265.94 describe how to install a ground-water monitoring system and do the sampling and analysis, recordkeeping, and reporting.

The Part 264 regulations include the first phase of the standards to be used to issue permits for hazardous waste treatment, storage, and disposal facilities. Included are requirements relating to preparedness for and prevention of hazards, contingency planning, and emergency procedures, the manifest system, and recordkeeping and reporting. Also included are general requirements relative to identification numbers, required notices, waste analysis, security at facilities, inspection of facilities, and personnel training.

In conformance with the recently enacted Solid Waste Disposal Act Amendments of 1980, EPA amended the regulations to exclude solid waste from the extraction, beneficiation, and processing of ores and minerals (including coal), including phosphate rock and overburden from the mining of uranium ore (3).

Effluent Guidelines

Parts 400 to 460 of Title 40 describe effluent guidelines and standards. These parts of the regulations were proposed pursuant to the Federal Water Pollution Control Act whereas the previous parts regarding hazardous wastes were promulgated based on the Solid Waste Disposal Act, as amended by the Resource Conservation and Recovery Act (RCRA) of 1976. These effluent guidelines give "effluent limitations" which means any restrictions established by EPA on quantities, rates, and concentrations of chemical, physical, biological, and other constituents which are discharged from point sources into navigable waters, contiguous zone of water or the ocean. The term "point source" means any discernible, confined and discrete conveyance from which pollutants are discharged. Here "pollutant" means solid waste and other industrial, municipal, and agricultural wastes discharged into water.

Section 401.15 lists toxic pollutants. In the list are base metals and compounds of arsenic, cadmium, copper, lead, mercury, selenium, silver, and zinc. Section 401.15 lists conventional pollutants such as grease and oil. Part 136 describes test procedures for pollutants.

EPA listed 21 industrial categories which were believed to discharge the pollutants of greatest environmental concern. Hydrometallurgical processes fall within two categories, ore mining and nonferrous metal manufacturing.

Subparts D, E, and F of Part 421 (nonferrous metals manufacturing category) deal with the categories of primary copper smelting, primary copper refining, and secondary copper refining, respectively. They do not apply to facilities recovering copper from the ore by hydrometallurgical methods.

Subparts G and H treat the categories of primary lead and primary zinc, respectively.

Subpart H is applicable to discharge resulting from the production of primary zinc by either electrolytic or "pyrolytic" means. Table 3, taken from Subpart H, shows effluent limitations guidelines representing the degree of effluent reduction attainable by the application of the best available technology economically achievable for the zinc industry according to EPA.

Section 440.22 (ore mining categories) gives effluent limitations guidelines for base and precious metals. It says for instance that there shall be no discharge of process water from vat leach processes for the extraction of copper from ores.

Application of the Regulations and EPA's Future Approach

Application

Residue toxicity varies widely with the materials processed and the process used. As an example of the hydrometallurgical process, the jarosite process was considered to treat a bulk concentrate of zinc, copper and lead. Jarosite was produced in the laboratory and subjected to the EP toxicity test. Table 4

shows the result of the test. As can be seen in the table, the jarosite in this case must be considered to be a toxic waste due to high concentration of lead.

From the processing point of view, it may be advantageous to dischard this residue outright. Contained metal values are comparatively minor, and furthermore the addition of water (as would be required for washings to recover values in the entrained liquid) could create extensive water balance problems. By definition the residues are hazardous unless the concentrations in the EP toxicity test are below those in Table 1. Of immediate concern in this respect is the residual liquid, which is considered part of the solid waste (section 261.2, "Other waste material is any solid, liquid, semi-solid or contained gaseous material....") and would be covered by the hazardous waste regualtions because of its metal content, in particular lead. Flexibility in the process design would be lost if recovery or removal of these metals were attempted and other options would need to be considered.

When the new hazardous regulations were promulgated on May 19, 1980, they did not exclude wastes from the processing of ores. In conformance with the recently enacted Solid Waste Disposal Act Amendments, EPA amended the hazardous regulations to exclude from the regulation solid wastes from the extraction, beneficiation and processing of ores(3). EPA, for the time being, is interpreting the scope of these exclusions broadly but is unsure that this interpretation is consistent with the intent of the Congress. EPA may further narrow the exclusion in subsequent rulemaking.

Even before the Congressional Amendment, EPA was aware that application of the full set of proposed waste management standards would not be appropriate for such wastes as beneficiation wastes, uranium and other mining wastes because (p. 33173 of Ref. 2):

1) The total annual quantity of each of these wastes is very large and individual disposal facilities tends to involve large piles or ponds. Should large volumes of the wastes be hazardous, the size of the facilities could make the application of some of the regulations technically infeasible or impracticable.
2) Any portion of the wastes which fail the proposed hazardous waste characteristics are thought to be on the margin of failure. Thus the hazardous portions of the wastes appear to have relatively low intrinsic hazard relative to other wastes.
3) EPA does not have sufficient information to propose specific alternate waste management requirements without additional studies.

Approach Taken by Environmental Protection Agency

The following comments on EPA's outlook are based on the Federal Register(4).

EPA is particularly concenred with the standards for land disposal facilities because of the effects of wastes on groundwater. EPA has begun to develop a comprehensive groundwater protection strategy that will guide many of its programs. In developing such a strategy, EPA examined four principal alternatives: facility design requirements, containment strategies, specific ambient health and environmental performance standards, and non-numerical health and environmental standards. Of these approaches, currently EPA intends to pursue the possibility of using specific design requirements in future regulations.

EPA could establish specific design requirements applicable to all land disposal facilities. For example, the regulations could require all landfills to install liners meeting minimum specification (e.g. the equivalent of 20 ft (6.1 m) of clay having a permeability of 10^{-7} cm/sec.), leachate collection systems capable of removing 98% of the leachate generated in the facilities, and highly impermeable covers. Also, EPA currently intends to use the approach of nonnumerical health and enfironmental standards that lay out broad objectives which permittees must seek to meet.

In the future, EPA will establish technical design requirements that reduce the risk of groundwater and surface water contamination. EPA will also require that disposal facilities do not degrade surface waters and groundwaters below certain established ambient health and environmental performance standards (e.g. water quality standards). EPA will use non-numerical health and environmental standards to protect against any potential adverse effects not addressed by the other types of standards.

EPA has developed a specific outline for protecting groundwater from the adverse effects of land disposal facilities(4). The key elements of the approach include:

1) It is unacceptable to allow a facility to cause any contamination of a down gradient water supply used for any purpose (drinking water, agricultural, industrial,etc.)
2) The regulations would require that the facility owner or operator employs certain management practices and design features that would control adverse effects on groundwater and surface water, as well as prevent or minimize other surface environmental effects.
3) While EPA believes that the non-degradation goal must be the starting point in the regulations, it recognizes that in some circumstances it may be possible to show that limited degradation will not adversely affect the public health or the environment.

EPA is considering applying this scheme to all new facilities.

Current Trend

The EPA is in the process of passing on to state environmental bodies the authority for enforcing hazardous waste handling regulations. EPA authorities estimate that

many States are ready to take up Resource Conservation and Recovery Act (RCRA) enforcement(5). However, some States may choose not to, in which case the federal agency will remain the enforcing body.

Each state is free to make its standards which should be at least equivalent to Federal standards. Some states set their standards even stricter than the Federal standards. For example, South Carolina has a toxicity standard of only ten times the Safe Drinking Water Act guidelines (Toxicity standard of Federal regulations is 100 times the Safe Drinking Water Act guidelines). Federal regulation defines a waste generator as any generator which produces more than 1000 kg/month of waste, New York's proposed definition of a waste generator is much stricter than EPA's, 100 kg/month. California applies a guideline based on chemical content. They have identified close to 900 hazardous substances, and something that contains one of these substances would be considered a hazardous waste. Therefore, we should look closely at this RCRA decentralization in the future.

Conclusion

Residues from hydrometallurgical processes are excluded temporarily from the new hazardous waste regulations. However, we have to follow the effluent limitations guidelines and also state and local environmental regulations.

It is not known yet whether EPA will resume implementation of the new hazardous regulations to the minerals industry or will make the current exemption permanent. EPA may propose modified regulations in the future. EPA lacks long-term experience with advanced waste management technologies. Therefore, it may take several years to adequately develop nationally applicable detailed technical standards on certain specific issues. EPA has begun to develop a comprehensive ground-water protection strategy and intends to pursue the possibility of using specific design requirements and several other strategies in promulgating new regulations. State authorities rather than federal are likely to play an important role in implementing hazardous waste handling regulations in the future.

Environmental Protection Agency

Ore Mining and Dressing Point Source Category Effluent Limitations Guidelines and New Source Performance Standards

ENVIRONMENTAL PROTECTION AGENCY

40 CFR Part 440

[WH-FRL 2232-1]

Ore Mining and Dressing Point Source Category Effluent Limitations Guidelines and New Source Performance Standards

AGENCY: Environmental Protection Agency (EPA).

ACTION: Final rule.

SUMMARY: This regulation limits the discharge of pollutants into navigable waters of the United States from exisitng and new sources in the ore mining and dressing industry. The Clean Water Act and a Consent Decree require EPA to issue this regulation.

The purpose of this regulation is to establish "best available technology" limitations (BAT) and "new source performance standards" (NSPS) for direct dischargers. Pretreatment standards for both existing and new sources are not being issued since no known indirect dischargers exist nor are any known to be planned. Effluent limitations for "best conventional technology" (BCT) are reserved pending application of the new BCT cost methodology.

DATES: In accordance with 40 CFR 100.01 (45 FR 26048), this regulation will be considered issued for purposes of judicial review at 1:00 P.M. Eastern time on December 17, 1982. It will become effective January 17, 1983 publication date, except § 440.104(b)(2)(ii) which contains information collection requirements which are under review at OMB.

Under Section 509(b)(1) of the Clean Water Act, any petition for judicial review of this regulation must be filed in the United States Court of Appeals within 90 days after the regulation is considered issued for purposes of judicial review. Under Section 509(b)(2) of the Clean Water Act, the regulation may not be challenged later in civil or criminal proceedings brought by EPA to enforce its requirements.

ADDRESS. Technical information may be obtained from Mr. B. Matthew Jarrett, at the address listed below, or by calling (202) 382-7164. The economic information may be obtained from Mr. John Kukulka, Office of Analysis and Evaluation (WH-586), Environmental Protection Agency, 401 M Street SW., Washington, D.C. 20460, or by calling (202) 382-5388.

On December 24, 1982, copies of the development document and the NSPS economic analysis will be available for public review in EPA's Public Information Reference Unit, Room 2404 (Rear) (EPA Library), 401 M Street SW., Washington, D.C. On February 7, 1983, the complete Record, including the Agency's responses to comments on the proposed regulation will be available for review at the Public Information Reference Unit. The EPA information regulation (40 CFR Part 2) allows the Agency to charge a reasonable fee for copying. Copies of the development document and the economic analysis may also be obtained from the National Technical Information Service, Springfield, Virginia 22161 (703) 487-6000. A notice will be published in the **Federal Register** announcing the availability of these documents from NTIS. (This should occur within 60 days of today's date.)

G. Pollutants Excluded by Subcategory and Subpart
H. Subcategories Excluded From Development of BAT or NSPS

I. Legal Authority

The regulations described in this notice are promulgated under authority of Sections 301, 304, 306, 307, 308, and 501 of the Clean Water Act (the Federal Water Pollution Control Act Amendments of 1972, 33 USC 1251 et seq., as amended by the Clean Water Act of 1977, P.L. 95-217) (the "Act"). These regulations are also promulgated in response to the Settlement Agreement in *Natural Resources Defense Council, Inc.*, v. *Train*, 8 ERC 2120 (D.D.C. 1976), *modified*, 12 ERC 1833 (D.D.C. 1979).

II. Scope of This Rulemaking

A. *Overview.* This regulation applies to facilities engaged in mining and processing of metal ores. The industry includes facilities which mine or process the ores of 23 separate metals and is segregated by the U.S. Bureau of the Census Standard Industrial Classification (SIC) into nine major codes: SIC 1011, Iron Ore; SIC 1021, Copper Ores; SIC 1031, Lead and Zinc Ores; SIC 1041, Gold Ores; SIC 1044, Silver Ores; SIC 1051, Aluminum Ore; SIC 1061, Ferroalloy Ores including Tungsten, Nickle, and Molybdenum; SIC 1092 Mercury Ores; SIC 1094 Uranium, Radium, and Vanadium Ores; and SIC 1099 Metal Ores, Not Elsewhere Classified including Titanium and Antimony.

Over 500 active mining and over 150 milling operations are located in the United States and most are in remote areas.

The industry includes facilities that mine ores to produce metallic products and all ore dressing and beneficiating operations at mills operated either in conjunction with a mine operation or at a separate location. A detailed overview of the ore mining industry can be found in the proposed regulation (47 FR 25682).

B. *Prior EPA Regulations.* On November 6, 1975, EPA published interim final regulations establishing BPT requirements for existing sources in the ore mining and dressing industry (see 40 FR 51722). These regulations became effective upon publication. However, concurrent with their publication, EPA solicited public comments with a view to possible revisions. On the same date, EPA published proposed BAT, NSPS, and pretreatment standards for this industry (see 40 FR 51738). Comments were also solicited on these proposals.

On May 24, 1976, as a result of the public comments received, EPA suspended certain portions of the interim final BPT regulations and solicited additional comments (see 41 FR 21191). EPA promulgated revised, final BPT regulations for the ore mining and dressing industry on July 11, 1978, (see 43 FR 29711, 40 CFR Part 440). On February 6, 1979, EPA published a clarification of the BPT regulations as they apply to storm runoff (see 44 FR 7953). On March 1, 1979, the Agency amended the final BPT regulations by deleting the requirements for cyanide applicable to froth flotation mills in the base and precious metals subcategory (see 44 FR 11546).

On December 10, 1979, the United States Court of Appeals for the Tenth Circuit upheld the BPT regulations, rejecting challenges brought by five industrial petitioners. *Kennecott Copper Corp.* v. *EPA*, 612 F. 2d 1232 (10th Cir. 1979).

The Agency withdrew the proposed BAT, NSPS, and pretreatment standards on March 19, 1981 (see 46 FR 17567). On June 14, 1982 the Agency proposed the BAT, BCT, and NSPS limitations and standards which are the subject of this rulemaking.

C. *Description of This Regulation.* As a result of the Clean Water Act of 1977, the emphasis of EPA's program has shifted from "classical" pollutants to the control of a list of toxic substances. Therefore, in this rulemaking, EPA efforts are primarily directed toward ensuring the achievement of limitations based upon the best available technology economically achievable (BAT) by July 1, 1984.

The BPT effluent limitations are included as part of this regulation for the convenience of the reader. Since there are no substantive changes in the BPT effluent limitations as sustained by the 10th Circuit, the BPT effluent limitations are not subject to further judicial review.

BAT limitations are established for seven subcategories in the ore mining and dressing point source category. The BAT effluent limitations are being promulgated as they were proposed on June 14, 1982 (47 FR 25682). The technology basis for BAT is discussed in the proposed regulation and is discussed in greater detail in the development document supporting the proposed regulation and in the development document supporting this final regulation.

BCT effluent limitations are not being promulgated in this rulemaking. As discussed further in Section V, Changes from Proposal, BCT for this point source category is instead being included as part of the proposed regulation on the new BCT cost methodology. (47 FR 49176, October 29, 1982).

NSPS are established for seven subcategories. A NSPS for froth flotation mills extracting copper, lead, zinc, gold, silver, or molybdenum was proposed as zero discharge, but the standard is being amended to allow for a bleed in the mill circuit. Also, the upset and bypass storm provision for new sources requiring zero discharge is being changed and made identical to the provision for existing sources. All other standards of performance and general provisions are established essentially as proposed. This is discussed further in Section V, Changes from Proposal.

Finally, this regulation does not establish pretreatment standards because, as discussed in the proposed regulation, the Agency knows of no existing facilities which discharge to publicly owned treatment works and does not expect that any new sources will do so.

III. Summary of Legal Background

A. *The Clean Water Act.* The Federal Water Pollution Control Act Amendments of 1972 established a comprehensive program to "restore and maintain the chemical, physical and biological integrity of the Nation's waters" (Section 101(a)). To implement the Act, EPA was required to issue effluent limitations guidelines, pretreatment standards and new source performance standards for industrial dischargers.

The Act included a timeable for issuing these standards. However, EPA was unable to meet many of the deadlines and, as a result, in 1976, it was sued by several environmental groups. In settling this lawsuit, EPA and the plaintiffs executed a court-approved "Settlement Agreement." This Agreement required EPA to develop a program and adhere to a schedule in promulgating effluent limitations guidelines and pretreatment standards for 65 "priority" pollutants and classes of pollutants, for 21 major industries. [*See Natural Resources Defense Council, Inc.* v. *Train*, 8 ERC 2120 (D.D.C. 1976), *modified*, 12 ERC 1833 (D.D.C. 1979)].

Many of the basic elements of this Settlement Agreement were incorporated into the Clean Air Water Act of 1977 ("the Act"). Like the Settlement Agreement, the Act stressed control of the 65 classes of toxic pollutants. In addition, to strengthen the toxic control program, Section 304(e) of the Act authorizes the Administrator to prescribe "best management practices" (BMP) to prevent the release of toxic and hazardous pollutants from plant site runoff, spillage or leaks, sludge or waste disposal and drainage from raw material storage associated with, or ancillary to, the manufacturing of treatment process.

Under the Act, the EPA program is to set a number of different kinds of effluent limitations. These are discussed in detail in the proposed regulation and development document. The following is a brief summary:

1. Best Practicable Control Technology Currently Available (BPT). BPT limitations generally are based on the average of the best existing performance at plants of various sizes, ages and unit processes within the industry or subcategory. In establishing BPT limitations, we consider the total control of applying the technology in relation to the effluent reduction derived, the age of equipment and facilities involved, the process employed, the engineering aspects of the control technologies, process changes and the nonwater-quality environmental impacts (including energy requirements). We balance the total cost of applying the technology against the effluent reduction.

2. Best Available Technology Economically Achievable (BAT). BAT limitations, in general, represent the best existing performance in the industrial subcategory or category. The Act establishes BAT as the principal national means of controlling the direct discharge of toxic and nonconventional pollutants to navigable waters. In arriving at BAT, the Agency considers the age of the equipment and facilities involved, the process employed, the engineering aspects of the control technologies, process changes, the cost of achieving such effluent reduction and nonwater-quality environmental impacts. The Administrator retains considerable discretion in assigning the weight to be accorded these factors.

3. Best Conventional Pollutant Control Technology (BCT). The 1977 Amendments added Section 301(b)(2)(E) to the Act establishing "best

conventional pollutant control technology" (BCT) for discharges of conventional pollutants from existing industrial point sources. Conventional pollutants are those defined in Section 304(a)(4) [biological oxygen demanding pollutants (e.g., BOD5) total suspended solids (TSS), fecal coliform and pH] and any additional pollutants defined by the Administrator as "conventional," i.e., oil and grease. (See 44 FR 44551: July 30, 1979.)

BCT is not an additional limitation but replaces BAT for the control of conventional pollutants. In addition to other factors specified in section 304(b)(4)(B), the Act requires that BCT limitations be assessed in light of a two part "cost-reasonableness" test. *American Paper Institute* v. *EPA*, 660 F. 2d 954 (4th Cir. 1981). The first test compares the cost for private industry to reduce its conventional pollutants with the cost of publicly owned treatment works (POTWs) for similar levels of reduction in their discharge of these pollutants. The second test examines the cost-effectiveness of additional industrial treatment beyond BPT. EPA must find that limitations are "reasonable" under both tests before establishing them as BCT. In no case may BCT be less stringent than BPT.

EPA published its methodology for carrying out the BCT analysis on August 29, 1979 (44 FR 50732). In the case mentioned above, the Court of Appeals ordered EPA to correct data errors underlying EPA's calculation of the first test, and to apply the second cost test. (EPA had argued that a second cost test was not required.)

EPA recently proposed a new methodology on October 29, 1982 and simultaneously proposed BCT limitations for ore mining and dressing. (47 FR 49176).

4. *New Source Performance Standards (NSPS).* NSPS are based on the best available demonstrated technology. New plants have the opportunity to install the best and most efficient production processess and wastewater treatment technologies.

5. *Pretreatment Standards for Existing Sources (PSES), and Pretreatment Standards for New Sources (PSNS).* Pretreatment standards (PSES and PSNS) are designed to control the discharge of pollutants into publicly owned treatment works. Pretreatment standards were not proposed for the ore mining and dressing category since no known indirect dischargers exist nor are any known to be planned. Ore mines are located in rural areas, generally far from a POTW. EPA expects that the cost of pumping mine and mill wastewater to a POTW would be prohibitive in most cases, and on-site treatment is more cost effective in virtually every instance.

IV. Methodology and Data Gathering Efforts.

The methodology and data gathering efforts used in developing the proposed regulation were discussed in the preamble to the proposal, 47 FR 25682 (June 14, 1982). In summary, before publishing the proposed regulation the Agency conducted a data collection, analytical screening, and analytical verification program for the ore mining and dressing industry. This program stressed the acquisition of data on the presence and treatability of the 65 toxic pollutants and classes of toxic pollutants discussed previously. The 65 toxic pollutants and classes of pollutants potentially include thousands of specific pollutants. EPA selected 129 specific toxic pollutants for study in this rulemaking and other industry rulemakings. (Analytical methods are discussed in *Sampling and Analysis Procedures for Screening of Industrial Effluents for Priority Pollutants* (U.S. E.P.A., April 1977)). Based on the results of that program, EPA identified several distinct treatment technologies, including both end-of-pipe and in-plant technologies, that are or can be used to treat ore mining and dressing industry wastewaters.

For each of these technologies, the Agency (i) compiled and analyzed historical and newly-generated data on effluent quality, (ii) identified its reliabilities and constraints, (iii) considered the nonwater quality impacts (including impacts on air quality, solid waste generation and energy requirements), and (iv) estimated the costs and economic impacts of applying it as a treatment and control system. Costs and economic impacts of the technology options considered are discussed in detail in two separate documents. *The Economic Impact Analysis of Promulgated New Source Performance Standards for the Ore Mining and Dressing Industry* and *The Economic Impact Analysis of Promulgated BAT Effluent Limitations and Standards for the Ore Mining and Dressing Industry.* A more complete description of the Agency's study methodology, data gathering efforts and analytical procedures supporting the regulation can be found in the *Final Development Document for Effluent Limitations Guidelines and New Source Performance Standards for the Ore Mining and Dressing Point Source Category* (U.S. EPA, November 1982).

V. Summary of Promulgated Regulation and Changes From Proposal

The final regulation does not change the proposed BAT regulations but does change the standards for new sources. The changes are the result of the Agency's consideration of public comments provided in response to the proposal and further evaluation of the information upon which the proposal was based.

A. *Subcategorization.* The proposed subcategorization scheme was similar to the subcategorization scheme found in the 1978 BPT regulations. That scheme subcategorizes the industry primarily on the basis of ore type. Each subcategory is further subdivided on the basis of whether the discharge is from a mine or a mill and, in some cases, according to the type of beneficiation process employed. In these final regulations the Agency is retaining the proposed subcategorization scheme with a few modifications resulting from comments received on the proposed regulation.

The 1978 BPT regulations contained a Ferroalloy Ores subcategory that addressed discharges from facilities mining or milling chromium, cobalt, columbium, tantalum, manganese, molybdenum, nickel, tungsten, and vanadium (recovered alone, rather than as a by-product of uranium mining or milling). The BPT regulations also contained a Base and Precious Metal Ores subcategory that addressed the discharges from facilities mining or milling copper, lead, zinc, gold, or silver. Prior to proposing the BAT and NSPS regulations, EPA found that the wastewater discharges from molybdenum mines and mills were more like the discharges from facilities in the Base and Precious Metals Ores subcategory than the discharges from the Ferroalloy subcategory. Consequently the proposed BAT and NSPS regulations placed molybdenum mines and mills into the Base and Precious metals subcategory, which was renamed the Copper, Lead, Zinc, Gold, Silver, Platinum and Molybdenum Ores subcategory. The proposal also eliminated the Ferroalloy subcategory and replaced it with the Nickle Ores subcategory, the Tungsten Ores subcategory, and the Vanadium Ores subcategory (recovered alone, not as a by-product of uranium mining and milling). For clarification, however, the proposal retained the old subcategorization scheme for the BPT limitations.

From the comments received, it is apparent that retention of the old BPT subcategorization scheme for the BPT

limitations has only confused, rather than clarified matters. The commenters suggested that, to eliminate this confusion, the Agency should use an identical subcategorization scheme for all the limitations and standards. Accordingly, in this final regulation, the Agency is eliminating a separate subcategorization scheme for the BPT limitations, and is, instead, using the same scheme for all the BPT, BAT, and NSPS limitations. This change is solely for the purpose of clarification and will not alter in any way the actual numerical limitations which apply to facilities covered by the BPT regulations.

One additional modification to the subcategorization scheme is being made. The Agency is taking platinum ore out of the new Copper, Lead, Zinc, Gold, Silver, and Molybdenum Ores subcategory and establishing a new subcategory for these mines and mills. The Agency received comments that a new platinum mine and mill is being considered that will be substantially different than the existing mines and mills upon which the Agency based best demonstrated technology. The Agency is, therefore, establishing a new subcategory addressing platinum ore mines and mills and is reserving the new source performance standard.

B. Applicability. As discussed in the proposal, the Ore Mining and Dressing effluent guidelines limitations and standards are applicable to facilities discharging wastewater from ore mining and milling operations. They do not, however, provide a complete basis for calculating the limitations of operations known as "complex facilities," which combine wastestreams from processes such as refining and smelting with ore mining and milling wastestreams and then treat this combined stream before discharge. Each facility will be given effluent limitations that are derived from the BAT mine and mill guidelines and the smelter and refining guidelines and other applicable guidelines.

The Agency received voluminous comments from developers of a molybdenum mine and mill in southeastern Alaska. The developers argued that the mill differs substantially from the existing molybdenum mills upon which the Agency based the proposed NSPS. Specifically, they argue that precipitation is greater than at other facilities and that the terrain is unusually steep, necessitating the construction of a dam much larger than tailings impoundments at existing facilities. They further argue that since the mine and mill are located in the environmentally sensitive Misty Fjords National Monument, construction of a massive tailings impoundment may result in greater long term environmental degradation than at existing facilities. In a related vein, they point out that the mine and mill are being developed in accordance with the dictates of the Alaska National Interest Lands Conservation Act (ANILC), which requires an intensive study of the overall environmental impact of the mine and mill before construction begins. Finally, they note that the mine and mill are in an earthquake area, and that construction of a large tailings dam raises concerns for safety of the population below the dam.

The Agency disagrees with the commenter's assertions that the proposed molybdenum mine and mill differ significantly in topography and climate from existing mines and mills. Nevertheless, given the possibility that compliance with the zero discharge NSPS would result in substantial non-water quality environmental impacts, and given the fact these impacts are being subjected to an intense environmental scrutiny, the Agency believes it would be premature to subject the mine and mill to regulation at this time, before the environmental review process is fully completed.

Also, as the Agency stated in the preamble to the BPT regulations and in the proposed regulation for BAT and NSPS, under no circumstances will an owner or operator be required to violate applicable safety standards to meet the requirements of BPT, BAT, or NSPS. As discussed in these regulations, the Agency is confident that the national applicable effluent limitations guidelines and standards of performance do not pose a concern for the overall safety related to the water impoundments that may be required by the regulations. However, it would be premature to regulate this mine and mill before the potential for earthquake and avalanches in a deep mountain terrain has been completely evaluated by Federal and State agencies and others responsible for conducting a thorough study of the impacts of this proposed new mine and mill. Accordingly, the Agency is excluding this mine and mill from the regulations applicable to molybdenum mines and mills, thereby postponing consideration of the appropriate limitations for this facility until the permit proceedings.

The BPT limitations established a subpart for gold placer mines, but reserved effluent limitations because the Agency did not have sufficient technical or economic data. The proposal similarly reserved effluent limitations and standards for the gold placer mine subpart because the data generated prior to proposal were not sufficiently comprehensive.

EPA still has no data upon which to base an economic assessment of gold placer mines and does not have sufficient technical data to promulgate or propose limitations for gold placer mines. The Agency is, therefore, continuing to reserve the subpart for gold placer mines in the promulgated regulation.

C. Best Practicable Technology Limitations. The BPT limitations for the ore mining industry were promulgated in 1978, were completely upheld in the Courts, and are repeated in this regulation solely for clarity. EPA received a few comments which recommended that the Agency relax the current BPT regulations. These comments are discussed in the response to public comments document.

D. Best Available Technology Limitations. EPA proposed BAT limitations equal to the BPT regulations currently applicable to this industry.

The rationale for setting BAT effluent limitations equivalent to BPT effluent limitations is discussed in the proposal (47 FR 25682), the development document supporting the proposed rule, and the development document supporting this final rule. In summary, the Agency established BAT equal to BPT either because BPT already specified zero discharge of process wastewater, or because application of candidate BAT did not reduce the level of the toxic or nonconventional pollutants, or because BPT removed a very high percentage of the relevant pollutants. Almost all the commenters agreed with EPA's decision to propose BAT equal to BPT. Accordingly, the Agency is finalizing the BAT limitations as proposed. The comments addressing the BAT limitation are discussed in the response to public comments document.

E. Best Conventional Technology Limitations. The Agency proposed BCT limitations equal to the BPT limitations for conventional pollutants. This was done even though the Agency had not established a new cost effectiveness test for conventional pollutant removal as directed by the Fourth Circuit Court of Appeals decision in *American Paper Institute* v. *EPA*, F. 2d (4th Cir. 1981). In the proposal the Agency reasoned that since BPT is the minimum level of control required by law, no possible reassessment of BCT pursuant to the Court's remand could result in BCT limitations for conventional pollutants less stringent than the BPT limitations.

A number of commenters took issue with the Agency's decision to propose BCT limitations in the absence of a new BCT methodology. The Agency agrees with these criticisms and has accordingly decided to withdraw the BCT limitations proposed on June 14, 1982. Instead, BCT Limitations for the ore mining and dressing point source category are being included as part of the proposed regulation on the new BCT methodology. This proposed regulation was published in the **Federal Register** on October 29, 1982. (47 FR 49176). Comments on the proposed BCT limitations must be submitted during the comment period for the BCT rulemaking.

F. New Source Performance Standards. EPA proposed new source performance standards (NSPS) equal to the BAT limitations for all elements of the ore mining and dressing industry with the exception of froth flotation mills in the copper, lead, zinc, gold, silver, platinum and molybdenum subcategory and the uranium mill subcategory. The Agency proposed NSPS requiring zero discharge for these latter two segments as discussed below.

1. Froth Flotation Mills. The proposed zero discharge requirement for new froth flotation mills was based on the fact that 46 out of 90 existing facilities for which we have data achieve zero discharge through total recycle and evaporation of process wastewater.

Industry commenters raised a number of objections to this proposal. First, they argued that most of the mills achieving zero discharge are in net evaporation areas with flat topography and that it was inappropriate to extrapolate from the treatment performance of mills in these areas to mills located in rainy or mountainous areas. They contended that in rainy or mountainous areas, the costs of constructing the tailings impoundment necessary to achieve zero discharge and the costs of transporting recycle water back to the mill could be prohibitive. They implied that this problem was greatly exacerbated by the proposed storm exemption for new sources, which granted relief to a facility only upon the occurrence of a ten year, twenty-four hour storm.

Second, they argued that EPA improperly assumed that new sources, unlike existing sources, would not experience extensive retrofit costs. They pointed out that the Agency's proposed definition of new source embraces both virgin or "greenfield" facilities and facilities constructed in conjunction with existing sources. These latter facilities, they stated, will incur substantial retrofit costs to achieve zero discharge.

Finally, they asserted that the Agency neglected to take into account the buildup of reagents and other contaminants in the recycle water of a total recycle system. They claimed that these contaminants would interfere with the froth flotation process and cause severe loss of product, necessitating either the addition of fresh make up water or the treatment of the recycle water. They added that treating the recycle water may not always prove to be an effective solution because of the buildup of contaminants from the treatment of the recycle water. They pointed out the Agency had not calculated the costs of treating the recycle water or building the bigger impoundment to hold and recycle the wastewater.

The Agency disagrees with the commenters' first criticism that EPA failed to adequately take into account topographical and climatic constraints in proposing a zero discharge requirement for new sources. Mills currently achieving zero discharge are located in areas ranging from flat to extremely steep and mountainous. Zero discharge is thus demonstrated for a wide spectrum of topographical constraints. Similarly, although the majority of mills achieving zero discharge are located in dry areas, 15 are located in relatively wet areas. Zero discharge is thus demonstrated for wet areas as well as dry areas. Moreover, the standards promulgated for new source froth flotation mills allow a discharge of wastewater equivalent to the net precipitation (precipitation less evaporation) subject to the discharge limitations for mine drainage, e.g. 440.104(2)(i). By permitting the discharge of excess rainwater and runoff, this provision substantially minimizes the effect of climate on a facility's ability to meet zero discharge.

An assumption of the commenters' arguments is that the zero discharge requirement imposes significantly greater costs than the BPT requirement under the same set of topographical, climatic and land availability constraints. Many commenters implied that constructing a tailings pond necessary to achieve zero discharge in mountainous or rainy areas would be much more expensive than constructing a similarly situated pond to meet BPT requirements. Although there might have been some merit to this argument under the Agency's proposed storm exemption for new sources, this is no longer the case. Now that the Agency has amended the proposed storm provision to make it identical to the provision for existing sources, the pond required to meet BPT requirements will be approximately the same size as the pond required to meet zero discharge. (See Development Document for further discussion).

One commenter, whose existing tailings pond is located several miles from the mill and several thousand feet below it, argued that, if this mill were a new source, the costs of recycling water to the mill to achieve zero discharge would prove much more expensive than meeting the BPT requirements. The Agency, however, considers such situations to be extremely rare. If a new source had to operate under similar constraints, the Agency would entertain a petition to modify the new source standard or create a new subcategory for this type of facility.

With respect to industry commenters' second criticism, EPA agrees with their claim that there would be retrofit costs associated with meeting zero discharge where a new source is constructed at the site of an existing source. It is not clear, however, whether this problem is anything but theoretical. EPA specifically asked industry to provide it with examples of construction at the site of an existing source which might constitute a new source under EPA's proposed criteria for "new source" (45 FR 59343, September 9, 1980). After evaluating these examples, EPA has concluded that only one of the examples provided by industry would constitute a "new source" under the proposed criteria—and this example involved construction at a "green field" site. (These examples are specifically discussed in the Response to Comments document). Nevertheless, EPA has redone its economic analysis to embrace situations where construction at the site of an existing source would clearly create a new source (i.e. total replacement of a mill). EPA has concluded that in such situations, the costs of achieving zero discharge will not cause an adverse economic impact.

EPA agrees with the commenters' third contention that we did not adequately consider the buildup of contaminants in the recycle water. Commenters have come forward with data demonstrating that the buildup of reagents and other contaminants can in fact interfere with the extractive process, causing severe loss of product. They have also demonstrated that treatment of the recycle water may not always be an economically viable option for dealing with this interference problem. Unfortunately, this interference is a complex phenomenon, which appears to be related to the characteristics of the ore at particular sites, making it impossible to carve out a subcategory of facilities afflicted with this problem. Accordingly, to

accommodate the problem, the final NSPS contains a special "bleed" provision which will allow facilities to discharge wastewater (subject to the NSPS mine drainage standards) if they can demonstrate to the permitting authority that total recycle would cause a major interference in the extractive metallurgical process and that appropriate treatment of recycle water is not adequate to remedy this interference. This provision will allow such facilities to substitute some fresh water for recycle water as industry stated and their data indicated was necessary, thereby avoiding the losses associated with buildup of contaminants in the recycle water. Specification of the exact amounts of water discharged and the appropriate treatment of recycle water will, of course, be left to the permitting authority. The Agency has, however, evaluated the costs and economic impact of at least two forms of treatment of recycle water. The first is pH adjustment (lime addition) and settling. Assuming a 24-hour retention time and a 10 percent safety factor, the Agency has concluded that the costs of such treatment of recycle water would not be significant enough to deter investment for a new mill with a tailings pond used for primary settling. The Agency has further determined that additional treatment consisting of a mixed media filter would not constitute a barrier to entry for such mills. The development document and economic document supporting this regulation discuss in more detail the Agency's considerations in creating the bleed provision and what treatment was considered as appropriate treatment of recyle water.

2. Uranium Mills. The Agency proposed zero discharge for new uranium mills based on data demonstrating that 18 of 19 existing mills do not discharge wastewater. The single existing mill which discharges, recycles over 80 percent of the requirement for its intake water. Zero discharge for new uranium mills is based on recycle, evaporation, and a combination of recycle and evaporation.

Industry commented that our data represented mills in arid areas and that we did not consider new mills that may locate in areas of high rainfall. They also requested that flexibility should be allowed to accommodate changes in the extractive processes currently used to recover uranium. Finally they commented that we should allow an effluent discharge because such a discharge is considered a valuable commodity in water short areas.

The ability of uranium mills to achieve zero discharge is well demonstrated and is recognized by Federal and State regulating authorities dealing with the uranium industry. It is true that existing uranium mills are located in arid areas. However, we know of no plans for construction of new mills in non-arid areas, although some firms have conducted exploration in such areas. Should any new mills locate in areas of high net precipitation, they can take advantage of the net precipitation provision and the storm exemption. If, despite these provisions, a uranium mill locates in an area where it is impossible to achieve zero discharge the facility can petition the Agency to change NSPS or create a separate subcategory for that type of facility.

The Agency does not believe that it needs to provide any additional flexibility to accommodate changes in the extractive processes used to recover uranium. Industry commenters failed to provide EPA with any information concerning new or different extractive processes. Furthermore, the current regulations only apply to certain identified extractive processes and thus would not apply to processes unrelated to processes used today.

Nor does the Agency believe that the zero discharge requirement will adversely affect water conservation. Even if there were a slight increase in water consumption attributable to compliance with zero discharge, that increase would not be significant when compared to the benefits derived from the use of recycle and evaporation systems. Accordingly, the zero discharge requirement for new uranium mills is promulgated as proposed.

3. *Storm Exemption.* The Agency proposed a storm exemption for new sources subject to zero discharge which would allow a discharge of excess wastewater upon the occurrence of a 10-year 24-hour precipitation event. Industry stated that the provision of the exemption imposed an impossible design requirement on them and should be changed to the requirement for existing sources.

After reviewing the industry comments, and data developed by the Agency, EPA has concluded that the industry comments are valid. Conditioning the storm exemption on the actual occurrence of a 10-year, 24-hour storm is inappropriate because overflows can occur from facilities designed, maintained, and operated to handle a 10-year, 24-hour precipitation event as a result of recurring storms or excessive snowmelt even though no individual event were equivalent to a 10-year, 24-hour precipitation event. The proposal would have required facilities to engage in the extremely difficult task of anticipating all such combinations of precipitation events. Accordingly, we have modified the storm exemption for new sources subject to zero discharge so that it is identical to the exemption for existing sources.

The Agency received requests for further explanation of the considerations to be taken into account in the design and construction of a facility which may be granted relief under the storm exemption. As a result of these requests we have made some clarifying changes in the language of the exemption. The first change is designed to clarify the nature of the operator's responsibilities during an upset or bypass overflow event. The storm exemption is designed to provide a limited exception to the requirements applicable to mines and mills under normal operating conditions. It grants relief from excess discharges which occur during and immediately after any precipitation or snowmelt—the intensity of the event is not specified. The storm exemption was not intended to grant the operator the option of ceasing or reducing efforts to contain or treat the runoff resulting from a rainfall or snowmelt, i.e., the operator does not have the option of turning off the lime feed to a facility at the start of or during a precipitation event, regardless of the design and construction of the facility. The operator must, instead, take all reasonable steps during and after the precipitation event to treat or contain the wastewater discharge and to limit the amount of overflow or excess discharge.

The second change is intended to clarify the nature of the design requirement for sources subject to a zero discharge limitation and to emphasize the fundamental differences between that requirement and the requirement for sources not subject to zero discharge. The storm exemption applicable to sources which are allowed to discharge requires the facility to be able to contain the maximum volume of wastewater which would be generated by the facility during a 24-hour period plus the volume of water which would result from a 10-year, 24-hour rainfall or treat the flows associated with these volumes. The rationale behind the containment requirement is that a facility with such capacity, even if full at the beginning of the storm, would be able to treat the storm runoff and normal plant discharge by providing at least a 24-hour retention time for settling

of the wastewaters before the water is discharged.

The design concept for the storm exemption applicable to sources subject to zero discharge requirements must, however, be different, because such sources are not permitted to discharge. Such sources must, therefore, be able to contain the amount of water equal to the volume of water in the pond under normal operating conditions (which includes water which is recycled or will be evaporated) plus the volume generated from a 10-year, 24-hour rainfall. In other words, the source must provide a freeboard over and above normal pond levels which can accommodate the water generated by a 10-year, 24-hour rainfall. Simply being able to hold the normal volume of wastewater from the mill process without discharge plus the 10-year, 24-hour rainfall will not suffice, unless the normal process wastewater is a fair measure of the volume of water in the pond under normal operating conditions.

The third change is designed to clarify the relationship between the storm exemption and the general upset and bypass provisions set in the consolidated permit regulations [See, 40 CFR 122.60]. The relationship between them should be set out more clearly. In the preamble to the proposal, we said that the storm exemption supersedes the general upset and bypass provisions with respect to precipitation events; that is, an operator wishing to obtain an excursion from the BAT or NSPS requirements during precipitation events must comply with the the prerequisites of the storm exemption. We did not, however, state whether an operator also had to comply with any of the upset and bypass provisions contained in the consolidated permit regulations as well. To clarify this, the storm exemption is being changed to specifically require compliance with the notice provisions of the general upset and bypass provisions, in accordance with the Agency's original intent. In addition, we have added a sentence to clarify that the storm exemption, like the general upset and bypass provision, simply provides an affirmative defense to an enforcement action. Consequently, the burden of proving compliance with the conditions of the storm provision rests with the operator, just as in the case of the general upset and bypass exemptions.

Additional explanation of the storm exemption is offered in the development document supporting this rulemaking.

G. *General Provisions and Definitions.* As the result of the comments received on the proposed BAT and NSPS, the Agency is adding a definition for "in situ leach methods" applicable to the Uranium, Radium and Vanadium Ores subcategory. This definition makes it clear that the no discharge standard of performance for in situ leach methods is applicable to the process wastewater used in and resulting from the actual in situ operation itself. In situ mine and mill process wastewater does not include discharges from wells from within or surrounding in situ mines used to restore aquifers after all actual mining activity (extraction of the ore, or pregnant liquor from the in situ process) has been completed. Such discharge would be from an inactive mine area and effluent limitations guidelines and standards of performance would not be directly applicable. Effluent limitations and standards are directly applicable to "active mining areas." During the actual working of the mine, if the discharge originates from an area outside of the in situ process area but directly associated with the "active mine area" such discharges are considered "mine drainage" and are subject to the effluent limitations or standards of performance for mine drainage from uranium mines. Mine drainage from areas outside of the areas used for the in situ process area include: drainage from development areas of a deep mines, and surface mine and runoff from mine and mill areas that are not directly involved in in situ leaching. Additional explanation is offered in the development document supporting this rulemaking.

The Agency received comments requesting that the Agency further explain the general provision having to do with waste streams which are combined for treatment from various subparts and segments of Part 440. We stated in the original provision that the quantity and quality of each pollutant or pollutant property in the combined discharge shall not exceed the quality and quantity of each pollutant or pollutant property that would have been discharged had each waste stream been treated separately. Further, the flow from the combined discharge shall not exceed the volume that would have been discharged had each wastestream been treated separately. An example that industry wished clarified is whether mine drainage commingled with the discharge from a new froth flotation mill is subject to the zero discharge requirements for new froth flotation mills. Such combined waste streams may be discharged subject to the limitations on mine drainage but the volume of the discharge cannot exceed the volume of mine drainage that would have been discharged had the mine drainage and the mill discharge been treated separately. It is immaterial whether the mine drainage is introduced to the treatment system simultaneously with the discharge from the mill, e.g. two separate pipes leading to the tailings pond, or whether the mine drainage is introduced as part of the feed water and intake to the mill itself. Further explanation and guidance is provided in the development document supporting this final regulation.

One commenter suggested that EPA provide a special allowance, similar to the net precipitation provision, for underground water which seeps into the tailings impoundment, this commenter asserted that such seepage constituted a large portion of the water collecting in its impoundment. The Agency knows of only this one example of underground seepage at existing facilities subject to zero discharge and believes that the fundamentally different factors variance provision provides an avenue of relief for existing sources. To accommodate new sources, however, the Agency is adding a provision which will allow the permit writer to grant an additional discharge allowance in the case of significant groundwater infiltration, subject to the limitations on mine drainage.

There were requests from industry that a separate definition for "new source" applicable to ore mines and mills be included in the final regulation. The Agency feels that there is no reason to do so. As part of the consolidated permit regulations, Paragraph 122.66(b), the Agency promulgated criteria for determining what is a new source. On September 9, 1980, these criteria were withdrawn and new criteria were proposed. When finalized, these criteria will apply to the mining industry.

VI. Costs and Economic Impact

Executive Order 12291 requires EPA and other agencies to provide regulatory impact analyses for rules that result in an annual cost to the economy of $100 million dollars or more, cause major price increases to the consumer and cause significant adverse effects on competition, employment, investment, productivity and the balance of trade. In addition, the Clean Water Act specifies that best available technology limitations must be economically achievable. The Regulatory Flexibility Act requires EPA to consider the effects of this rule on small entities, and if they are significant and affect a substantial number of small entities, to prepare a Regulatory Flexibility Analysis. The Agency has concluded that this is not a major rule and will not have a significant impact on a substantial number of small entities and, therefore,

a Regulatory Impact Analyses and a Regulatory Flexibility Analysis are not required.

The BAT limitations promulgated today do not reflect any treatment requirements beyond the treatment required for existing direct dischargers under the BPT rule promulgated July 11, 1978 (43 FR 29711). Additionally, EPA is not establishing pretreatment standards because no known indirect dischargers exist nor are any known to be in the planning stage. Accordingly, EPA expects no incremental costs or impacts for existing plants from this rulemaking. The costs for New Source standards are not expected to be a deterrent to investment and are not expected to change the rate of entry into the industry or slow the industry growth rate.

In developing this rule, the Agency considered various technology options and analyzed their economic impacts. This economic analysis is presented in two documents. One is the *Economic Impact Analysis of Promulgated New Source Performance Standards for the Ore Mining and Dressing Industry* which addresses new sources. The second document is *The Economic Impact Analysis of Promulgated BAT Effluent Limitations Guidelines for the Ore Mining and Dressing Industry* which addresses existing sources and is presently subject to a confidentiality requirement discussed previously. For each of the options considered during rulemaking, these analyses detail the investment and annual costs for the industry as a whole and for typical plants; assesses the impact of effluent control in terms of price and production changes, plant closures and employment effects; and assesses the potential impacts on the small plants in this industry.

VII. Nonwater Quality Environmental Impacts

The elimination or reduction of one form of pollution may aggravate other environmental problems. Therefore, sections 304(b) and 306 of the Act require EPA to consider the nonwater quality environmental impacts (including energy requirements) of certain regulations.

In compliance with these provisions, EPA has considered the effect of these regulations on air pollution, solid waste generation, land requirements, water consumption and energy requirements.

Because this regulation does not impose any additional pollution control requirements on existing sources, implementation will not result in any substantial increase in air pollution, energy use, solid waste generation, land requirements or water consumption.

The Agency similarly, determined that the pollution control requirements for new sources, where they differ from existing sources requirements, will not result in adverse non-water quality impacts which would require alteration of the requirements.

In those subparts for which NSPS is more stringent than BAT, the increase in solid waste generated should not be greater than one percent.

In addition, section 7 of the Solid Waste Disposal Act Amendments of 1980 has exempted under Subtitle C of RCRA solid waste from the extraction, beneficiation, and processing of ores and minerals. This exemption will remain in effect until at least six months after the Administrator submits a study on the adverse environmental effects of solid waste from mining. The study is required to be submitted by October 21, 1983 (see 42 U.S.C. 6982).

Imposition of NSPS is not expected to create any significant adverse impacts on land requirements beyond those associated with BAT effluent limitations.

Achievement of NSPS will not result in a significant net increase in energy requirements. The main use of energy is for pumping, mixing, and control instrumentation. Wherever feasible, gravity flow is used in treatment facilities for mine drainage and mill process wastewater. Recycle at new froth flotation mills and new uranium mills will require electric power for pumps, but the Agency concludes that the impact of the energy consumed from compliance with the standards is justified by the benefits derived from the standards.

There should be no net water loss attributable to compliance with zero discharge of process wastewater from froth flotation mills and uranium mills. Moreover, even if there were a slight loss, it would not be significant when compared to the benefits derived from the use of recycle and evaporation systems.

VIII. Pollutants and Subcategories Not Regulated

Paragraph 8 of the modified Settlement Agreement, approved by the District Court for the District of Columbia on March 9, 1979 (12 ERC 1833), contains provisions authorizing the exclusion from regulation, in certain circumstances, of toxic pollutants and industry categories and subcategories.

A. Exclusion of Pollutants. As discussed in greater detail in the proposal June 14, 1982 and in the development document supporting the rule, paragraph 8[a][iii] of the Revised Settlement agreement allows the Administrator to exclude from regulation toxic pollutants not detectable by Section 304(h) analytical methods or other state-of-the-art methods. This provision includes pollutants below EPA's nominal detection limit. In addition, Paragraph 8[a][iii] allows the exclusion of pollutants that were detected in amounts too small to be effectively reduced by technologies known to the Administrator. Pollutants excluded under these provisions are listed in Appendices B, C and D. One hundred and thirteen toxic organics, cyanide and six toxic metals are excluded from regulation under these provisions.

Paragraph 8[a][iii] also allows the Administrator to exclude from regulation pollutants detected in the effluent of only a small number of sources within the category and uniquely related to those sources. The toxic organic pollutant, 2,4-dimethylphenol, was detected in the effluent at only one facility and 2,4-dimethylphenol is excluded under this provision.

Paragraph 8[a][iii] also allows the Administrator to exclude from regulation pollutants that are effectively controlled by the technology upon which other effluent limitations and guidelines are based. Effluent limitations for TSS will effectively control the toxic pollutant asbestos (chrysotile). Arsenic and nickel found in discharges from ore mining and dressing are adequately controlled by the incidental removal associated with the control and removal of other metals found in the discharges from this industry, e.g., copper, lead, mercury, and zinc.

In addition to the toxic pollutants excluded for all subcategories, EPA is excluding certain toxic pollutants from particular subcategories and subparts because they were either not detected or detected in amounts too small to be effectively reduced by technologies known to the Administrator. See Appendix G for pollutants excluded by subcategory and subpart.

B. Exclusion of Subcategories. Paragraph 8(a)(iv) of the revised settlement Agreement allows the Administrator to exclude a category or subcategory from regulation if the amount and toxicity of each pollutant in the discharge does not justify developing national requirements in accordance with the schedule contained in the agreement. EPA is excluding the mill subpart in the Uranium, Radium and Vanadium subcategory from development of BAT regulations

ecause there is only one existing ischarger and development of national egulations are not warranted for this ngle plant. EPA is excluding the Nickel ubcategory, the Vanadium subcategory nined alone and not as a byproduct) nd, the Antimony subcategory from evelopment of BAT and NSPS because here is only one known discharger in ach of these subcategories and no new ources are expected. EPA is excluding he Platinum subcategory from evelopment of NSPS because the one lentified new source must use an ntirely different treatment system than hat was identified as best emonstrated technology and EPA lacks ata on the system. EPA is differing egulations of the gold placer mine ubpart of the Copper, Lead, Zinc, Gold, ilver, and Molybdenum subcategory ntil it completes data gathering efforts or this subpart.

Paragraph 8(b) of the Settlement greement allows the Administrator to xclude from regulation pretreatment tandards for all point sources within a oint source category. Pretreatment tandards for both existing and new ources in this point source category are ot justified because no indirect ischargers exist nor are any known to e planned.

X. Best Management Practices

Section 304(e) of the Clean Water Act ives the Administrator authority to rescribe "best management practices" BMPs). BMPs are not addressed in this egulation.

X. Upset and Bypass Provisions

A recurring issue is whether industry uidelines should include provisions uthorizing noncompliance with effluent imitations during periods of "upset" or "bypass." An upset, sometimes called an "excursion," is an unintentional oncompliance occurring for reasons beyond the reasonable control of the permittee. It has been argued that an upset provision in EPA's effluent imitations is necessary because such upsets will inevitably occur even in properly operated control equipment. Because technology-based limitations require only what technology can achieve, it is claimed that liability for such situations is improper. When confronted with this issue, courts have disagreed on whether an explicit upset or excursion exemption is necessary, or whether upset or excursion incidents may be handled through EPA's exercise of enforcement discretion. Compare *Marathon Oil Co.* v. *EPA*, 564 F. 2d 1253 (9th Cir. 1977) with *Weyerhaeuser* v. *Costle*, 590 F. 2d 1011 (D.C. Cir. 1978) and *Corn Refiners Assn., et al.* v. *Costle*, 594 F. 2d 1223 (8th Cir. 1979). [See also *American Petroleum Institute* v. *EPA*, 540 F. 2d 1023 (10th Cir. 1976); *CPC International, Inc.* v. *Train*, 540 F. 2d 1320 (8th Cir. 1976); *FMC Corp.* v. *Train*, 539 F. 2d 973 (4th Cir. 1976).]

An upset is an unintentional episode during which effluent limits are exceeded; a bypass, however, is an act of intentional noncompliance during which waste treatment facilities are circumvented in emergency situations. We have, in the past, included bypass provisions in NPDES permits.

We determined that both upset and bypass provisions should be included in NPDES permits and have promulgated Consolidated Permit Regulations that include upset and bypass provisions. [See 40 CFR 122.60, 45 FR 33290 (May 19, 1980).] The upset provision establishes an upset as an affirmative defense to prosecution for violation of technology-based effluent limitations. The bypass provision authorizes bypassing to prevent loss of life, personal injury, or severe property damage.

The Agency has received several inquiries on the relationship between the general upset and bypass provisions set forth in the consolidated permit regulations and the storm exemption contained in the regulations for ore mining and dressing. This relationship is discussed in Section V of this preamble.

XI. Variances and Modifications

Upon the issuance of this regulation, the effluent limitations for the appropriate subcategory must be applied in all Federal and State NPDES permits thereafter issued to direct dischargers in the ore mining and dressing industry. For the BPT effluent limitations promulgated on July 11, 1978, the only exception to the binding limitations is EPA's "fundamentally different factors" variance. [See *E.I. du Pont de Nemours & Co.* v. *Train*, 430 U.S. 112 (1977); *Weyerhaeuser Co.* v. *Costle*, *supra*.] This variance recognizes factors concerning a particular discharger that are fundamentally different from the factors considered in this rulemaking. Although this variance clause was set forth in EPA's 1973–1976 industry regulations, it is now included in the NPDES regulations and will not be included in the ore mining and dressing industry BAT regulation. (See the NPDES regulations at 40 CFR Part 125, Subpart D.)

The BAT limitations in this regulation are also subject to EPA's "fundamentally different factors" variance. BAT limitations for nonconventional pollutants are subject to modifications under Sections 301(c) and 301(g) of the Act. These statutory modifications do not apply to toxic or conventional pollutants. To apply for these modifications a discharger must be in compliance with BPT. Because this rule will make BAT equal to BPT, EPA does not expect any applications for Section 301(c) or 301(g) modifications. [See 43 FR 40895 (September 13, 1978).] NSPS are not subject to EPA's "fundamentally different factors" variance or any statutory or regulatory modifications. [See *E. I. du Pont de Nemours and Co* v. *Train*, supra.)

XII. Relationship to NPDES Permits

The BAT limitations and NSPS in this regulation will be applied to individual ore mines and mills through NPDES permits issued by EPA or approved state agencies, under Section 402 of the Act. As discussed in the preceding section of this preamble, these limitations must be applied in all Federal and State NPDES permits except to the extent that variances and modifications are expressly authorized. Other aspects of the interaction between these limitations and NPDES permits are discussed below.

One issue that warrants consideration is the effect of this regulation on the powers of NPDES permit-issuing authorities. The promulgation of this regulation does not restrict the power of any permitting authority to act in any manner consistent with law or these or any other EPA regulations, guidelines or policy. For example, even if this regulation does not control a particular pollutant, the permit-issuer may still limit such pollutant on a case-by-case basis when limitations are necessary to carry out the purposes of the Act. Where manufacturing practices or treatment circumstances warrant additional controls, such limitations may be technology-based in conformance with the legislative history of the Act. However, such limitations are subject to administrative and judicial review as part of the permit issuance process. In addition, to the extent that State water quality standards or other provisions of State or Federal law require limitation of pollutants not covered by this regulation (or require more stringent limitations on covered pollutants), such limitations must be applied by the permit-issuing authority.

A second topic that warrants discussion is the operation of EPA's NPDES enforcement program, many aspects of which were considered in developing this regulation. We emphasize that although the Clean Water Act is a strict liability statute, the initiation of enforcement proceedings by EPA is discretionary. We have exercised

and intend to exercise that discretion in a manner that recognizes and promotes good-faith compliance efforts.

XIII. Public Participation

The Agency solicited public comment on the proposed rules published in the Federal Register on June 14, 1982, (47 FR 25682). In addition, the Agency accepted public comment on the development document and economic analysis supporting the proposed rules. The Agency received over fifty comment submittals.

Individual public comments received on the proposed regulation, and our responses, are presented in a report, "Responses to Public Comments, Proposed Ore Mining and Dressing Industry Effluent Guidelines and Standards," November 1982, which is part of the public record for this regulation.

Most of the major comments and the Agency's response are discussed in Section V of this preamble, Summary of Promulgated Regulation and Changes from Proposal.

XIV. Small Business Administration (SBA) Financial Assistance

The Agency is continuing to encourage small manufacturers to use Small Business Administration (SBA) financing as needed for pollution control equipment. Three basic programs are in effect: the Guaranteed Pollution Control Program, the Section 503 Program, and the Regular Guarantee Program. All the SBA loan programs are only open to businesses with net assets less than $6 million, with an average annual after-tax income of less than $2 million and with fewer than 250 employees.

The guaranteed pollution control program authorizes the SBA to guarantee the payments on qualified contracts entered into by eligible small businesses to acquire needed pollution control facilities when the financing is provided through pollution control bonds, bank loans and debentures. Financing with SBA's guarantee of payment makes available long-term financing comparable with market rates. The program applies to projects that cost from $150,000 to $200,000.

The Section 503 Program, as amended in July 1980, allows for long-term loans to small and medium-sized businesses. These loans are made by SBA-approved local development companies, which for the first time are authorized to issue Government-backed debentures that are bought by the Federal Financing Bank, an arm of the U.S. Treasury.

Through SBA's Regular Guarantee Program, loans are made available by commercial banks and are guaranteed by the SBA. This program has interest rates equivalent to market rates.

For additional information on the Regular Guarantee and Section 503 Programs contract your district or local SBA Office. The SBA coordinator at EPA headquarters is Ms. Frances Desselle who may be reached at (202) 382-5373.

For further information and specifics on the Guaranteed Pollution Control Program contact: U.S. Small Business Administration, Office of Pollution Control Financing, 4040 North Fairfax Drive, Rosslyn, Virginia 22203, (703) 235-2902.

XV. List of Subjects in 40 CFR Part 440

Metals, Mines, Water pollution control, Waste treatment and disposal.

XVI. Availability of Technical Assistance

The justification for the proposed regulation is detailed in four major documents available from EPA. Analytical methods are discussed in (1) *Sampling and Analysis Procedures for Screening of Industrial Effluents for Priority Pollutants.* EPA's technical conclusions are detailed in the (2) *Development Document for Final Effluent Limitations Guidelines and New Source Performance Standards for the Ore Mining and Dressing Point Source Category.* The economic analysis for new sources is detailed in *Economic* (3) *Analysis of New Source Performance Standards for the Ore Mining and Dressing Industry.* The economic analysis for existing sources is detailed in the *Economic Impact Analysis of* (4) *Promulgated BAT Effluent Limitations Guidelines for the Ore Mining and Dressing Point Source Category.* The data contained in the analysis is covered by a third party agreement between the Agency and industry members who supplied the data. These data are confidential and can not be released until cleared by a confidentiality review panel. The Agency anticipates the BAT economic analysis will be made available to the general public shortly after this rule is promulgated.

A summary of the public comments received on the proposal and EPA's responses is presented in "Summary of (5) Comments and Responses on the June 1982 Proposed Regulations for the Ore Mining and Dressing Industry," which is part of the public record for this regulation.

XVII. OMB Review

The regulation was submitted to the Office of Management and Budget for review as required by Executive Order 12291.

In accordance with the Paperwork Reduction Act of 1980 (P.L. 96-511), the reporting or recordkeeping provisions that are included in this regulation will be submitted for approval to the Office of Management and Budget (OMB). They are not effective until OMB approval has been obtained and the public notified to that effect through a technical amendment to this regulation.

Dated: November 5, 1982.

Anne M. Gorsuch,
Administrator.

APPENDIX A

Abbreviations, Acronyms and Units Used in This Notice

Act—The Clean Water Act.

Agency—The U.S. Environmental Protection Agency.

BADT—Best available demonstrated technology under sections 304(c) and 306.

BAT—The best available technology economically achievable, under section 304(b)(2)(B) of the Act.

BCT—The best conventional pollutant control technology, under section 304(b)(4) of the Act.

BMP's—Best management practices under section 304(e) of the act.

BPT—The best practicable control technology currently available, under section 304(b)(1) of the Act.

CWA—The Federal Water Pollution Control Act Amendments of 1972 (33 U.S.C. 1251 et seq.) as amended by the Clean Water Act of 1977 (P.L. 95-217).

FWPCA—Federal Water Pollution Control Act.

MSHA—The Department of Labor, Mine Safety and Health Administration.

NPDES Permit—A National Pollutant Discharge Elimination System permit issued under section 402 of the Act.

NSPS—New source performance standards under section 306 of the Act.

POTW—Publicly owned treatment works.

RCRA— Resource Conservation and Recovery Act (PL 94-580) of 1976, Amendments to Solid Waste Disposal Act.

UNITS

gpd—gallons per day.
mgd—million gallons per day.
mg/l—milligram(s) per liter.
µg/l—microgram(s) per liter.

APPENDIX B

Toxic Organic Compounds Not Detected During Sampling

1. Acenaphthene.

2. Acrolein.
3. Acrylonitrite.
4. Benzidene.
5. Carbon Tetrachloride.
6. 1,2,4-Trichlorobenzene.
7. Hexachlorobenzene.
8. 1,2-Dichloroethane.
9. Hexachloroethane.
10. 1,1-Dichloroethane.
11. 1,1,2-Trichloroethane.
12. 1,1,2,2-Tetrachloroethane.
13. Chloroethane.
14. Bis(Chloromethyl) Ether.
15. Bis(2-Chloroethyl) Ether.
16. 2-Chloroethyl Vinyl Ether.
17. 2-Chloronaphthalene.
18. 2,4,6-Trichlorophenol.
19. Parachlorometa Cresol.
20. 2-Chlorophenol.
21. 1,2-Dichlorobenzene.
22. 1,3-Dichlorobenzene.
23. 1,4-Dichlorobenzene.
24. 3,3-Dichlorobenzidene.
25. 1,1-Dichloroethylene.
26. 2,4-Dichloro-phenol.
27. 1,2-Dichloropropane.
28. 1,3-Dichloropropylene.
29. 2,4-Dinitrotoluene.
30. 2,6-Dinitrotoluene.
31. 1,2-Diphenylhydrazine.
32. Fluoranthene.
33. 4-Chlorophenyl Phenyl Ether.
34. 4-Bromophenyl Phenyl Ether.
35. Bis(2-Chloroisopropyl) Ether.
36. Bis(2-Chloroethoxy) Methane.
37. Methyl Chloride.
38. Methyl Bromide.
39. Bromoform.
40. Dichlorodifluoromethane.
41. Chlorodibromomethane.
42. Hexachlorobutadiene.
43. Hexachlorocyclopentadien.
44. Isophorone.
45. Naphthalene.
46. Nitrobenzene.
47. 2-Nitrophenol.
48. 4-Nitrophenol.
49. 2,4-Dinitrophenol.
50. 4,6-Dinitro-O-Cresol.
51. N-Nitrosodimethylamine.
52. N-Nitrosodiphenylamine.
53. N-Nitrosodi-N-Propylamine.
54. Benzo(A)Anthracene.
55. Benzo(A)Pyrene.
56. 3,4-Benzofluoranthene.
57. Benzo(K)Fluoranthene.
58. Chrysene.
59. Acenaphthylene.
60. Anthracene.
61. Benzo(G,H,I)Perylene.
62. Phenathrene.
63. Dibenzo(A,H)Anthracene.
64. Indeno(1,2,3-C,D)Pyrene.
65. Pyrene.
66. Trichloroethylene.
67. Vinyl chloride.
68. Chlordane.
69. 4,4-DDT.
70. 4,4-DDE.
71. 4,4-DDD.
72. Endosulfan-Alpha.
73. Endosulfan-Beta.
74. Endosulfan Sulfate.
75. Endrin Aldehyde.
76. Heptachlor Epoxide.
77. γBHC(Lindane)-Gamma.
78. PCB-1242 (AROCHLOR 1242).
79. PCB-1254 (AROCHLOR 1254).
80. PCB-1221 (AROCHLOR 1221).
81. PCB-1232 (AROCHLOR 1232).
82. PCB-1248 (AROCHLOR 1248).
83. PCB-1260 (AROCHLOR 1260).
84. PCB-1016 (AROCHLOR 1016).
85. Toxaphene.
86. 2,3,7,8-Tetrachlorodibenzo-p-Dioxin.

APPENDIX C

Toxic Organic Compounds Detected at Least One Facility but Always 10 μg/l or Less

1. Chlorobenzene.
2. Dichlorobromoethane.
3. Fluorene.
4. Aldrin.
5. Dieldrin.
6. Endrin.
7. Heptachlor.
8. 1,1,1-Trichloroethane.
9. Chloroform.
10. Ethylbenzene.
11. Trichlorofluoromethane.
12. Diethyl Phthalate.
13. Tetrachloroethylene.
14. Toluene.
15. αBHC-Alpha.
16. βBHC-Beta.
17. ΔBHC-Delta.

APPENDIX D

Toxics Detected at Levels Too Small To Be Effectively Reduced by Technologies Known to the Administrator

1. Antimony.
2. Beryllium.
3. Silver.
4. Thallium.
5. Selenium.
6. Chromium.
7. Cyanide.
8. Benzene.
9. 1,2-Trans-Dichloroethylene.
10. Phenol.
11. Bis(2-Ethylhexyl) Phthalate.
12. Butyl Benzyl Phthalate.
13. Di-N-Butyl Phthalate.
14. Di-n-Octyl Phthalate.
15. Dimethyl Phthalate.
16. Methylene Chloride.
17. Pentachlorophenol.

APPENDIX E

Toxic Organic Compounds Detected From a Small Number of Sources and Uniquely Related to These Sources

2,4-dimentylphenol.

APPENDIX F

Pollutants Effectively Controlled by the Technology Upon Which Other Effluent Limitations and Guidelines Are Based

1. Asbestos.
2. Arsenic.
3. Nickel.

APPENDIX G

Pollutants Excluded by Subcategory and Subpart

Uranium Ore Subcategory—Mine Drainage

Cadmium (not detected).
Copper (present in amounts too small to treat).
Lead (present in amounts too small to treat).
Mercury (present in amounts too small to treat).

Tungsten Ore Subcategory—Mine Drainage

Lead (not detected).
Mercury (present in amounts too small to treat).

Tungsten Ore Subcategory—Mill Process Water

Mercury (not detected).

Mercury Ore Subcategory)—Mine Drainage.

Cadmium (not detected).
Copper (not detected).
Lead (not detected).
Zinc (not detected).

Titanium Ore Subcategory—Mine Drainage

Cadmium (not detected).
Copper (present in amounts too small to treat).
Lead (present in amounts too small to treat).
Mercury (not detected).
Zinc (present in amounts too small to treat).

Titanium Ore Subcategory—Mine Drainage

Cadmium (not detected).
Copper (present in amounts too small to treat).
Lead (present in amounts too small to treat).
Mercury (not detected).

Titanium Ore Subcategory—Mill with Dredges

Cadmium (present in amounts too small to treat).
Copper (present in amounts too small to treat).
Lead (present in amounts too small to treat).
Zinc (present in amounts too small to treat).

CLEAN WATER ACT—REGULATORY UPDATE

by

James R. Walpole
Partner, Holland & Hart

INTRODUCTION

Several years ago I presented a paper to this group describing the Clean Water Act requirements on mining operations, and we all know these requirements continue to increase. This year I have been asked to mention some of the notable regulatory developments under the act that have occurred during the past year. In the time available, it is not possible to discuss these matters in any detail so I will outline the developments and try to answer any question during the question and answer period.

By way of background, the Clean Water Act was originally passed in 1948 and has been amended numerous times since then. The most important amendments occurred in 1972, 1977 and 1978. The law as it is now written is designed to improve and maintain the quality of the nation's waters by eliminating the discharge of pollutants, by providing for the protection and propagation of fish, shellfish and wildlife and providing for recreation, and by prohibiting the discharge of toxic pollutants in toxic amounts. It directs the Environmental Protection Agency (EPA) to issue a wide range of standards and regulations for the control of discharges into U.S. waters from point sources (e.g., pipes, ditches, discrete conveyances) and non-point sources (e.g., runoff). An individual state may assume some of EPA's permitting authority if it submits an acceptable plan to the agency. The act also directs the Corps of Engineers to control the program that regulates the dredge and fill material in so-called "wetland" areas.

EFFLUENT GUIDELINES

The law prohibits the discharge of pollutants into waters of the U.S. without a permit. To obtain a permit, a person must agree to comply with effluent guidelines which are, generally speaking, EPA regulations that define the level of wastewater treatment a facility must provide before a discharge is allowed. These guidelines limit the amount of pollutants that can be discharged from a point source. These standards apply nationally and can be revised at any time.

National effluent guidelines have been set for more than 40 industrial categories, including ore mining and dressing, coal mining, smelting and refining, iron and steel, cement manufacturing, explosives manufacturing, and oil and gas extraction. They contain limitations for such things as total suspended solids, oil and grease, manganese, iron, copper, zinc, pH, COD and cadmium. I would now like to focus my remarks on the recently published proposed or final effluent guidelines for ore mining and dressing, smelting and refining, and coal mining. The regulations contain several levels of treatment that are specifically defined in the act: best practicable control (BPT),[1] best available control (BAT),[2] best control of certain conventional pollutants (BCT),[3] standards of performance for new sources (NSPS).[4] Those of you familiar with Clean Water Act permits no doubt are familiar with these.

Ore mining and dressing

Between 1975 and 1979 EPA issued effluent guidelines for ore mining and dressing facilities that required the application of the best practicable control technology currently available (BPT). They contained requirements for facilities processing: iron ore, base and precious metals (such as copper, lead, zinc, gold

and silver), aluminum, ferroalloy ores, uranium, radium, vanadium, mercury and titanium. These regulations were modified July 11, 1978 and Mar. 1, 1979.[5] Last year, on June 14, EPA proposed three sets of regulations for the ore mining and dressing industry: BAT standards, BCT standards and standards for new sources (NSPS).

There were several items of concern to the industry in the proposed regulations which were reviewed carefully by the American Mining Congress staff and members of its Water Quality Control Subcommittee. Probably the major concern was in regard to the new source performance standards for copper, lead, zinc, gold, silver, platinum and molybdenum processing. The proposed standards required zero discharge for the facilities.

The AMC comments pointed out that wastewater management technologies in the mining industry have a number of constraints, including climate, topography, geology, hydrology, land availability, waste management requirements. They went on to describe technical reasons why zero discharge was not an appropriate standard, and requested a variance provision be included in the regulations.

The final regulations were issued Dec. 3, 1982 and contained requirements for processing iron ore, aluminum ore, tungsten ore, nickel ore, vanadium ore mined alone, antimony ore, copper, lead, zinc, gold, silver and molybdenum ores, and platinum ore. The preamble to the regulations specifically recognized that a build-up of contaminants in the recycle water can significantly interfere with ore recovery and cannot be eliminated through appropriate treatment of the recycle water. The regulations now provide that the permitting authorities may allow a discharge of the process wastewater in the amount necessary to correct the interference problem after installation of appropriate treatment facilities.[6]

Smelting and refining

Another important set of effluent guidelines are those for smelting and refining. Between 1975 and 1980, EPA issued a series of BCT and BAT guidelines for the nonferrous metals manufacturing point source category, which is generally referred to as the "smelting and refining" category.[7] This category includes bauxite refining, primary aluminum smelting, secondary aluminum smelting, primary copper smelting, primary copper refining, secondary copper processing, primary lead smelting and refining, primary zinc processing, and metallurgical acid plants associated with certain processing operations.

On Feb. 17, 1983 EPA published proposed effluent guidelines as well as proposed new source performance standards, pretreatment standards for existing sources, pretreatment standards for new sources, and BCT effluent guidelines.[8] In addition to the subcategories listed above, the proposal adds the following subcategories: primary tungsten processing, primary columbium-tantalum processing, secondary silver processing, and secondary lead processing.

The February 1983 proposal addresses the 12 subcategories listed above and is the "Phase I" portion of the smelting and refining guidelines. Later this year, EPA intends to publish Phase II proposed regulations containing an additional 21 primary metals, 15 secondary metals and bauxite refining.

The proposal contains provisions of significant concern to smelting and refining facilities, especially primary copper, lead and zinc facilities. One major concern is that the data base used by EPA in developing the proposed regulations ignores wastewater chemistry and effluent reduction achievements occurring at existing facilities. Also, EPA reviewed and relied to some extent on data from other industries in developing the smelting and refining guidelines. AMC objected to this data in comments submitted to EPA and in fact provided the agency with further, extensive wastewater data developed by the Water Quality Subcommittee.

The proposed regulations require, among other things, reductions in concentration of pollutants and flow rate of effluent streams. However, many existing facilities simply cannot be operated in such a way as to reduce the concentration and flow to the limits proposed. Further, the EPA proposal would require lime and settle treatment as well as the additional requirement of filtering. This ignores the fact that several facilities have implemented tertiary treatment (such as filtering or polishing) without being able to meet the proposed limits. Another matter of concern is that the proposal would require segregation of stormwater to prevent it from flowing into treatment facilities. However, any existing plants treat combined process water and stormwater, and the operators question the effectiveness, as well as the cost, of installing separate stormwater systems.

AMC staff and members of the Water Quality Control Subcommittee have met with EPA to discuss these and other concerns, although there is no indication at this time whether the proposal will be modified. It is expected that final regulations will be issued sometime in early 1984.

Coal mining

On Apr. 26, 1977, EPA issued BPT effluent guidelines for the coal mining category[9] and published new source performance standards for this category July 12, 1979.[10] Revisions of the BPT and standards for new sources were proposed Jan. 13, 1981 along with BCT effluent guidelines.[11] On Oct. 13, 1982 EPA issued revised BPT effluent guidelines and new source performance standards for the coal mining point source category along with BCT effluent guidelines.

These regulations were challenged by several parties in the U.S. Court of Appeals for the Fourth Circuit. Briefing was stayed in the case so that negotiations could take place. After months of negotiations, the parties reached agreement and filed a settlement agreement with the court Aug. 1, 1983. It requires EPA to propose and issue amendments to the regulations and also publish specified preamble language. Time does not permit me to provide details of this agreement although I will mention that some of the matters dealt with include the definitions of new source coal mines, coal refuse disposal piles, controlled surface mine discharge, and abandoned mines. The proposed regulations are expected soon. If the final regulation and accompanying preamble are consistent with the agreement, the challenges will be dismissed.

DREDGE AND FILL REGULATIONS

The Clean Water Act provides for the issuance of permits for the discharge of dredge and fill material into navigable waters at specified disposal sites. These permits are issued by the U.S. Army Corps of Engineers. EPA, however, is authorized to issue guidelines for the designation of disposal sites.

The act authorizes the corps to issue permits "for the discharge of dredged or fill material into the navigable waters," and the corps has defined the terms "dredge material," "discharge of dredge material," "fill material" and "navigable waters" quite broadly.[12] Depending on the location, various activities undertaken in connection with a mining operation may require a corps permit, including constructing a road or bridge to move equipment, constructing an office, mill or mining site, constructing a tailings pond or water storage area, diverting streams, or construction of tunnels or pipelines.

On Sept. 19, 1980, the corps proposed dredge and fill regulations[13] and on July 22, 1982 it issued regulations for its dredge and fill program.[14] The new regulations establish 25 types of general or "nationwide" permits for which no permit application is required for a qualifying operation. Nationwide permits are available for a number of activities related to mining, including certain work associated with surface coal mining, surveying activities (e.g., core sampling, seismic exploratory operations, plugging seismic shot and other exploratory-type bore holes), minor road crossing fills, certain structures associated with discharges permitted under the Clean Water Act, certain utility line construction, and structures on work associated with surface coal mining activities authorized under the Surface Mining Control and Reclamation Act.[15]

While the industry expressed some concern over individual provisions, the overall approach taken in the new regulations was strongly supported by the mining industry.

On December 22, 1982, sixteen environmental and conservation groups challenged the Corps of Engineers regulations and requested the court to declare a number of provisions invalid and to enjoin the corps from implementing or enforcing certain of the provisions.[16] Three of the nationwide permit regulations challenged are of interest to the mining industry: i.e., 1) for activities conducted above headwaters of streams and rivers, 2) for activities near isolated waters (not part of a surface tributary system) and 3) for surface coal mine activities authorized by the federal Office or Surface Mining.[17] AMC and several other industry groups petitioned to intervene in the case, and the plaintiffs have opposed intervention of some industry groups, including AMC. The court has scheduled a status conference for Sept. 16, 1983 to decide on a briefing schedule, consider motions for intervention and other matters. Preliminary settlement discussions have taken place among the parties but, as yet, no issues have been resolved.

Also, on May 12, 1983, the corps proposed another series of regulations regarding dredge and fill activities. The proposal deals with many aspects of the regulations including the reimposition of the 10-acre lake limitation for headwaters and isolated water permits, and the addition of two new categories of nationwide permits.[18] The public comment period closed Aug. 31, 1983, and it is not certain when the final regulations will be issued.[19]

NPDES DISCHARGE PERMIT REGULATIONS

In 1980 EPA issued a comprehensive set of regulations setting forth the administrative procedures and requirements for obtaining a discharge permit.[20] These regulations were very controversial and the subject of protracted litigation by many companies and trade associations. In June 1982, a settlement agreement was reached whereby EPA agreed to propose and then issue a number of modifications to the regulations. On Nov. 18, 1982 EPA proposed extensive changes to the permit regulations.[21] The proposal includes many significant matters including stormwater runoff, net vs. gross limitations, pre-permit construction, and evidentiary hearing procedures. Final agency action on the regulations is expected soon.

PROPOSED REVISIONS TO WATER QUALITY STANDARDS

The Clean Water Act provides for the establishment of water quality standards.[22] These standards define the water quality goals of a water body (or portion) by designating the use or uses to be made of the water, and by setting the criteria necessary to protect the uses. The standards are adopted by the states to fit individual bodies of water and are the foundation of a state's water quality management process. These EPA standards are important because state standards are based on them.

On Oct. 29, 1982, EPA proposed revisions to its water quality standard regulations. The proposal allowed consideration of site-specific factors affecting a water body and it allowed consideration of seasonal uses of a stream. While there were some problems with the proposal, AMC submitted comments that were generally favorable.

Since the proposal, however, legislation was introduced in the Senate and House designed to preempt any significant change by EPA of the existing water quality standard regulations. The legislation in the Senate would codify the "antidegradation" provision in the existing regulations limiting how a water body may be classified. It would also eliminate certain discretionary authority now residing with EPA. Consequently, there have been discussions between EPA and congressional staff on the matter to see if a compromise can be worked out. It appears if EPA will modify its proposed regulations, the Senate committee may be willing to withdraw its legislative proposals. Many people feel EPA will modify its regulations to avoid legislation on this matter. If the regulations are so changed, the agency may find it necessary to repropose the regulations rather than simply issuing final regulations. A Senate markup on the Clean Water Act legislation is scheduled for Sept. 15 when this item may be discussed.

EPA GROUNDWATER POLICY

Several federal laws contain provisions designed to reduce contamination of groundwater, e.g., Resource Conservation and Recovery Act, Safe Drinking Water Act, Superfund, Uranium Mill Tailings Radiation Control Act. During the last three or four years, EPA has attempted to develop an overall groundwater policy to coordinate and set priorities for groundwater protection efforts. For a variety of reasons, this policy has never been finalized.

Recently EPA administrator Ruchelshaus announced the establishment of a task force to look into the matter. It will have three responsibilities: 1) to assess the differences in major policies, regulations and operational practices of groundwater programs such as RCRA, UIC and Superfund; 2) to study how the agency should coordinate groundwater policy development and program implementation throughout the country and 3) to review EPA policies and actions in light of their effect on state programs to protect groundwater. A report is to be submitted this fall and the administrator will then select an appropriate operational plan for the agency.

Protection of groundwater is a matter of extremely high priority at EPA, so

the report of the task force will be an important indication how the agency staff views the problems and solution. Once the report is submitted, the admininstrator will decide on further action to be taken in the development of an overall agency policy. It will be important for members of the mining industry to follow closely the report of the task force and any subsequent action taken by the agency.

REVIEW OF ENVIRONMENTAL LEGISLATION IN THE 98TH CONGRESS

by

David C. Ridinger
Vice President, Government Relations
Newmont Mining Corp.

The advent of the Reagan administration and the confirmation of Anne Gorsuch (now Burford) as EPA administrator in 1981 gave the industrial community great hope for sweeping rewrites of the environmental laws due for reauthorization. After nearly two years of lengthy hearings and emotional debate, the 97th Congress adjourned at the end of 1982 without having passed any comprehensive environmental amendments into law. Widespread publicity surrounding allegations of mismanagement at the Environmental Protection Agency in the beginning of 1983 led to a reorganization of key EPA personnel and increased public fears of pollutants in the environment. Now the 98th Congress is reluctant to pass any amendments that could be perceived as being "pro-industry" and appears to be heading toward passage of further restrictive and complicated controls.

Following is a review of five of the major areas of environmental legislation -- Clean Air, Clean Water, Safe Drinking Water, RCRA and CERCLA (Superfund) -- and their status in the 98th Congress.

CLEAN AIR

To properly review the current status of Clean Air Act amendments, it may be helpful to briefly highlight some of the activities of the 97th Congress in 1981 and 1982.

The Clean Air Act, along with the Clean Water Act and RCRA, was due for reauthorization in 1981, and both the Senate and House seemed eager to, and did, schedule hearings early in the session in an attempt to get the legislative process in motion. Following confirmation of the Reagan administration's EPA appointments, industry representatives approached Congress armed with lists of Clean Air Act amendments. Little did we realize that the reauthorization of the nation's major air pollution control law would turn into a bitter confrontation, with business and industry groups in constant conflict with environmental and public health groups.

The Senate Environment and Public Works Committee approved a bill in August 1982 that made modest changes in the existing Clean Air Act and added new provisions aimed at controlling acid rain and hazardous air pollutants. The Senate bill was met with mixed emotions by both the environmentalists and industry. Sections of the bill pertaining to acid rain, prevention of significant deterioration (PSD), hazardous air pollutants, visibility, etc. were unacceptable to industry. The environmentalists felt that the bill did not go far enough and were particularly opposed to an amendment in the Senate bill giving nonferrous smelters relief under Sec. 119. Although the Senate committee was able to report its bill to the Senate floor, very little time remained for the full Senate to consider the measure, and it died a natural death at the end of the 97th Congress.

On the House side, Henry Waxman's (D-CA) Subcommittee on Health and Environment kept a bill stalled for over 15 months before reporting its version to the full Energy and Commerce Committee. At the committee level, chairman John Dingell (D-MI) was expected to shepherd Waxman's version through a series of corrective amendments supported by industry, most of which were contained in a bill authored by Tom Luken, Democrat from Ohio. To chairman Dingell's surprise -- in fact, to the surprise of many of the environmentalists as well -- he was defeated on several key amendments, often by a mere one or two vote margin. The committee did manage to pass a nonferrous smelter amendment similar to the one contained in the Senate bill. However, on the very day the Senate committee ordered its bill reported, the Energy and Commerce Committee deadlocked on a hazardous air pollutants amendment. The House committee never resumed mark-up after that day and never reported a Clean Air bill during the 97th Congress.

This brings us to 1983 and a new Congress, the 98th, and some new committee members to deal with. In the 1982 election, liberal Democrats picked up a number of seats on the Energy and Commerce Committee, and the mining industry lost a valued supporter with the defeat of Jim Santini in his race for the Senate.

Although the 1982 election left the Republican numerical majority in the Senate intact, the Senate Environment and Public Works Committee picked up two more pro-environmentalist members. Since key votes on air act amendments were won or lost by only a one or two vote margin last year, even a slight shift or increase in the "swing" voters on either committee is significant. The Reagan administration, which disappointed industry during the last Congress by failing to come forth with a legislative package, is treading cautiously again this year, and it has given no clear signal that it will present specific legislative recommendations to Congress this time around, with the possible exception of acid rain.

Only one comprehensive Clean Air Act amendment bill has been introduced in Congress this year -- S. 768 -- introduced by Sen. Robert Stafford (R-VT), chairman of the Environment and Public Works Committee. S. 768 is essentially the same as the bill that the committee reported in 1982 and contains the same provisions for controlling acid rain, hazardous air pollutants, PSD and visibility. No hearings have been held on this year's bill. It appears that the Senate committee is waiting for some sign of activity from the House before embarking on the lengthy hearing and mark-up process. There have been reports that Congressmen Dingell and Waxman are collaborating on drafting Clean Air Act amendments for unveiling later this month. It is speculated that Dingell and Waxman intend to negotiate out of the spotlight of public hearings and mark-ups this year. A Dingell-Waxman compromise bill is probably the only vehicle that would stand a chance of moving through the factioned Energy and Commerce Committee.

Although there has been only one comprehensive Clean Air bill introduced this year, there have been numerous legislative initiatives specifically aimed at controlling acid rain. Following is a summary of proposed acid rain control strategies pending in Congress:

S. 768 and S. 769 by Stafford (R-VT)

S. 768 is the Environment and Public Works Committee bill mentioned above. One of its worst features is an acid rain provision that would require a reduction of eight million tons per year of sulfur dioxide emissions to be achieved over a 12-year period.

The purpose of S. 769, also by Sen. Stafford, is to raise the ante to 12 million tons per year over 15 years and to place caps on SO_2 and NO_x emissions by the year 2000. Both bills apply to a 31-state region east of the Mississippi.

S. 766 by Randolph (D-WV)

This bill calls for the submission of a report to Congress by August 1987, with recommendations on how to deal with acid rain. During the reporting period, the bill would place a cap on SO_2 emissions from all stationary sources at actual 1982 levels, assuming the bill passes in 1983. The Randolph bill applies to a 48-state region.

S. 145 by Mitchell (D-ME), H.E. 132 by Gregg (R-NH) and H.R. 2794 by St. Germain (D-RI)

These are identical bills, requiring a 10 million ton reduction in annual SO_2 emissions within 10 years of enactment. All three bills apply to a 31-state region.

S. 454 by Byrd (D-WV) and H.R. 1405 by Rahall (D-WV)

These identical bills require submission of a report to Congress by 1987, similar to the Randolph bill. Unlike the Randolph bill, however, the Byrd and Rahall bills do not place caps on SO_2 emissions. These bills also provide for mitigating grants to states or interstate agencies for neutralizing lakes, streams, etc.

H.R. 3251 by D'Amours (D-NH)

This bill calls for an 85 percent reduction in SO_2 emissions from the 50 largest power plants in the United States.

H.R. 3400 by Waxman (D-CA), Sikorski (D-MN) and Gregg (R-NH)

H.R. 3400 requires 48 states to collectively reduce SO_2 emissions by 10 million tons below 1980 levels by the year 1995. In addition, H.R. 3400 requires

the installation of scrubbers by the year 1990 on the 50 largest SO_2 emitting power plants in the U.S. that burn medium or high sulfur coal. The sponsors of the bill believe that the scrubber requirement would reduce SO_2 emissions by an additional seven million tons. Scrubbers are now only required on new plants. A scrubber requirement for existing plants would mean that utilities would have no incentive to switch to low-sulfur coal, according to the sponsors.

H.R. 3400 would establish a user fee on electricity generated from power plants in 48 states. The money would be channeled into a trust fund to reimburse utilities for 90 percent of the cost of installing scrubbers.

There have been reports that Sen. Durenberger (R-MN), a member of the Environment and Public Works Committee, is ready to introduce acid rain legislation calling for a 10 million ton SO_2 emissions reduction over 48 states. The costs of reduction would be funding by an emissions tax on SO_2 and NO_x nationwide.

There seems to be general agreement over only one aspect of the Clean Air debate: that there will be some kind of acid rain legislation passed by the 98th Congress before the Presidential elections, and quite possibly, before the end of 1983. The acid rain issue has become highly visible and political, and most legislators would rather have it out of the way before the campaigns heat up. Both House subcommittee chairman Waxman and Senate committee chairman Stafford are committed to passing an acid rain control program and will focus their attention on this issue as a prelude to a comprehensive look at Clean Air Act amendments. If acceptable compromises can be found for the controversial, and often uncertain, areas of the acid rain issue, the two committees may then consider the other Clean Air Act issues that divide their members in the 97th Congress, issues such as PSD, hazardous air pollutants, visibility and auto emissions.

CLEAN WATER

Prior to recessing in August, the Senate Committee on Environment and Public Works reported a bill to amend the Clean Water Act, the nation's principal law for controlling water pollution.

The bill, S. 431, was introduced by Sen. Chafee (R-RI) and is expected to be considered on the floor of the Senate this fall. As approved by the committee, S. 431 forces greater clean-up of water pollutants and rejects most of the Reagan administration's proposal to ease requirements on industrial and municipal dischargers.

On the House side, a Clean Water bill sponsored by James Howard (D-NJ), H.R. 3282, has been introduced but has not yet been considered by the Public Works Committee. However, the Public Works Committee chairman, Robert Roe (D-NJ), did not sign on as a co-sponsor to the Howard bill and is expected to hold hearings and mark-ups on his own set of Clean Water Act amendments this fall.

There are five major areas of the Clean Water debate:

BAT (best available technology)

A great deal of the Clean Water debate in 1982 centered around proposals to allow chemical and other industries to bypass tough technology requirements if they could demonstrate that less costly treatment (best practical technology) would not harm water quality. This year, the waiver of BAT requirements has been soundly rejected in both House and Senate bills. The environmental groups would like to require industrial dischargers to go even beyond BAT if the best technology fails to clean up polluted waters.

Pretreatment

In 1982, both municipal sewage treatment authorities and industries were on their way toward getting amendments passed that would allow the substitution of local pollution control programs for national pretreatment requirements governing industries pumping wastes into public disposal systems. Proponents of this measure advocated placing more authority at the local level, so that publicly-owned treatment works could tailor their programs to their particular problems and avoid unnecessary or duplicate treatment of wastes first by industry, then by municipality. This year, Sen. Chafee's bill (S. 431) does not allow for any waivers for publicly-owned treatment works (POTWs), and Congressman Howard's bill (H.R. 3282) allows waivers only in very limited situations and only after strict tests are passed.

Some industries are still pushing for a pretreatment provision in the Senate bill, and the issue may come up as a floor amendment.

Non-point pollution

Control of non-point pollution -- that which runs off farm lands or city streets, for example -- was not much of an issue last year. This year, however, the Senate committee bill contains a comprehensive, $150 million annual program to control agricultural and urban water pollution. The House bill does not contain a provision for non-point controls, but the sponsor of that bill, Congressman Howard (D-NJ), has stated that he is working on a proposal that will reduce non-point pollution "as effectively as the Clean Water Act has dealt with point sources."

Sec. 404 dredge and fill permit program

The Sec. 404 dredge and fill permit program of the Clean Water Act is one of the few existing laws that provides for the protection of wetlands. Environmental groups have been trying hard to have this section of the law strengthened. Certain industry groups have been trying to have the definition of "wetlands" narrowed to apply to only truly navigable waters. Under the present law, anyone wanting to fill in a swamp for development, drill an oil well, expand a port or dump any material in a waterway must go through a lengthy and complicated process of obtaining a permit from the Army Corps of Engineers.

Senators Chafee (R-RI) and Bentsen (D-TX) have drafted amendments to the Senate Clean Water bill which they are expected to offer on the floor. These amendments would make it possible for the states to administer part of the dredge and fill permit program, strengthen the involvement of the Fish and Wildlife Service and the Commerce Department in permit issuing decisions, and bring Sec. 404 within the scope of the "citizens suits" provision of the Clean Water Act.

Water quality standards

There is a continuing dispute between the Senate Environment and Public Works Committee and the EPA over water quality standards. In October 1982, the EPA issued proposed regulations to revise the current water quality standards. These proposed new standards were greeted favorably by industry, but they were not acceptable to several members of Congress and the environmental community who viewed the regulations as "weakening" the Clean Water Act. The EPA is currently working on a revised set of standards, but it has not issued another notice of proposed rulemaking to date. As a result, both S. 431 and H.R. 3282 contain provisions to codify the existing stringent water quality standards. This amendment could be deleted from both bills if the EPA proposes new water regulations that are acceptable to both the Senate and House committees.

The Senate bill, S. 431, contains an additional provision that would allow for stormwater run -off at mining operations to be considered as "non-point source" and therefore not subject to point-source regulations, if such stormwater run-off does not contain mining contaminants. Efforts are being made to have this provision introduced as an amendment to the House Clean Water bill.

SAFE DRINKING WATER

A bill to amend the Safe Drinking Water Act was introduced by Dennis Eckart, Democrat from Ohio, and co-sponsored by Congressman Waxman (D-CA). This bill, H.R. 3200, would force the EPA to regulate more drinking water contaminants, accelerate enforcement efforts and take initial action to protect groundwater supplies.

Specifically, H.R. 3200 would:

- Require EPA to set standards within 18 months for 14 organic chemicals found in drinking water but currently unregulated;
- Require establishment of a monitoring program for up to 129 additional water pollutants which EPA is required to regulate under the Clean Water Act;
- Require lining and groundwater monitoring of surface impoundments and landfills;
- Severely restrict, and may totally prohibit, deep-well injection of hazardous wastes beneath formations containing drinking water aquifers;
- Expand the definition of "drinking water source" to include water which may be anticipated to be capable of supplying any public water system, if such system were to use advanced technology treatment that may become available;

- Provide money for technical assistance programs to help public water system operators to attain standards. Under the present regulations, systems which cannot afford to comply now are allowed variances from the standards and told to comply as soon as possible. This bill would set strict requirements for compliance.

- Provide grants to states to identify groundwater sources and begin planning for their protection and use.

H.R. 3200 is heavily supported by environmental and conservation groups, but most major industries are concerned that, among other restrictions, this bill could ban all underground injection of wastes -- now an important alternative to landfilling. Public water suppliers disagree with the bill's presumption that all organic chemicals found in drinking water are hazardous and must be regulated. No doubt there will be considerable debate on this issue before a final bill can be passed.

The Health and Environment Subcommittee held hearings on H.R. 3200 this past summer and is expected to begin mark-up later this month. The bill should reach the full Energy and Commerce Committee before the session ends. As yet, corresponding legislation has not been introduced in the Senate.

RCRA

RCRA is the principal law governing the management and disposal of hazardous waste. Like the Clean Air and Water Acts, RCRA was due for reauthorization in 1981. And, like the air and water issues, RCRA amendments became entangled in debate in the 97th Congress and had to be carried over into the 98th.

In 1982, the House passed a comprehensive RCRA reauthorization bill sponsored by Congressman Jim Florio (D-NJ) and intended, in his own words, to "close the loopholes" in the hazardous waste management system. However, a companion measure in the Senate died when the Environment and Public Works Committe could not reach a consensus on tightening regulations for generators of small quantities of hazardous waste.

This year, debate over RCRA amendments seems to be focusing not on whether requirements in existing hazardous waste management law should be narrowed but on how quickly that should be done. Both the Senate Committee on Environment and Public Works and the House Energy and Commerce Committee have already reported RCRA bills this year.

On May 12, Energy and Commerce unanimously approved Congressman Florio's (D-NJ) H.R. 2867, a bill to reauthorize RCRA and give the EPA control over an additional 40 million metric tons of hazardous waste per year. The bill was debated on the floor of the House for one day before the August recess and has not yet passed.

On July 28, the Senate Environment and Public Works Committee, by a vote of 14-1, approved S. 757, a RCRA reauthorization bill introduced by Sen. Chafee (R-RI), who was also the author of last year's RCRA effort.

This year the Senate bill is closer in content to the House version. Both bills contain provisions which would:

- Require EPA to issue regulations for small quantity generators of 100 kg of hazardous waste or more per month;

- Prohibit the disposal of liquid hazardous waste;

- Prohibit the land disposal of certain hazardous waste;

- Prohibit the underground injection of hazardous waste close to drinking water sources;

- Regulate the burning and blending of hazardous waste as fuel;

- Require land disposal operators to install double liners, leakage capture systems and underground monitoring systems as a condition to obtaining a permit or renewal of a permit.

The double liner requirement is a major concern for the mining industry. When the House continues its floor debate on RCRA, Congressman Billy Tauzin (D-LA) is expected to introduce an amendment which will remove mining wastes from the application of the double liner requirement by referring to the Bevill amendment. The Bevill amendment was added to RCRA in 1980 and defers regulation of mining and smelting wastes pending completion of a study by EPA. The Tauzin amendment will also

direct EPA to develop appropriate standards for each facility, together with groundwater monitoring. The sponsor fo the House RCRA bill, Congressman Florio, has indicated that he will support the Tauzin amendment on the floor. The Senate bill contains a committee-approved amendment by Sen. Simpson (R-WY) that retains the double liner requirement but allows EPA to exempt landfill operators, on a case-by-case basis, from installing double liners if it can be proven that an alternate method offers equal protection for ground and surface water. Another provision in the Senate bill instructs EPA to determine if double liners are appropriate for mine wastes and, if not, to develop alternative methods that are adequate to protect human health and the environment.

The small generator exemption is another major concern in both the Senate and House bills. Under current law, businesses which produce less than 1000 kg per month of hazardous waste are considered "small generators" and are not subject to RCRA regulations. The House bill, as reported out of committee, calls for regulating sources that produce as little as 100 kg of hazardous waste per month. It further requries that generators of 25 kg of hazardous waste or more must notify their transporters that the waste is hazardous.

When H.R. 2867 was debated on the floor of the House, several amendments were adopted in deference to requests by EPA to ease the enormous regulatory burden the bill would place upon that agency; however, the 100-kg regulation and the 25-kg notification requirements were kept in the House bill.

The Senate bill, S. 757, as reported by the committee, also requires the regulation of generators which produce 100 kg or more per month, but contains a 100-kg threshold (instead of the 25 in the House bill) for notification of hazardous waste shipments.

Another RCRA bill has been introduced, S. 1363, by Sen. Gary Hart (D-CO). In many areas, this bill is even more stringent than either S. 757 or H.R. 2867; it requires the use of best available technology for hazardous waste management and a waste-end tax on disposers of hazardous waste. Sen. Hart has offered some sections of his bill as amendments to S. 757 in committee, and some of them were adopted. He is expected to continue to offer amendments when the bill is debated on the Senate floor.

COMPREHENSIVE ENVIRONMENTAL RESPONSE, COMPENSATION AND LIABILITY ACT (CERCLA)

Congressman Florio has been quoted as saying that, without a tough RCRA, the way would be cleared for the creation of more abandoned hazardous waste sites. This, in turn, would mean a greater need for the Comprehensive Environmental Response, Compensation and Liability Act of 1980, better known as Superfund. Superfund is now a five-year, $1.6 billion program set to expire in 1985. It would appear that it is too soon for legislators to consider extending Superfund when other environmental laws are overdue for reauthorization, but recent public fears and prolific reports about toxic wastes in the environment have precipitated a major congressional review of EPA's Superfund program. Allegations that EPA officials mishandled the toxic waste clean-up program led to a major housecleaning at EPA this year and could lead to further tightening of federal laws governing hazardous and toxic materials.

Proposals have already been introduced to extend funding of Superfund and to expand the law to provide compensation to persons injured or diseased by exposure to toxic substances in the workplace. Among the bills under consideration is H.R. 3129, introduced by Claudine Schneider (R-RI) and Ron Wyden (D-OR), which would replace the existing Superfund fee on petrochemical feedstocks with a fee on land disposal of hazardous wastes. Similar bills have been introduced in the Senate by William Proxmire (D-WI) - S. 1779, and by Gary Hart (D-CO) - S. 860. Sen. Hart's RCRA bill, S. 1363, also contains a provision to levy a waste-end tax on the disposer, the proceeds of which would be used for Superfund clean-up. Environmental groups are strongly in favor of this approach, since it would place the costs of clean-up upon those disposing of the waste.

Other CERCLA bills, S. 816 by Senator Bradley (D-NJ) and H.R. 1615 by Representative LaFalce (D-NY) would extend Superfund to 1990 and greatly increase the present funding level of $1.6 billion.

Victim's compensation is another area of the Superfund debate. When the Superfund law was originally proposed in 1980, it contained a provision to allow those persons injured or diseased because of hazardous or toxic waste to be compensated from Superfund for their medical costs. This provision was dropped from the final law. At that time, legislators were fearful that countless claims would be lodged against the fund, at a considerable cost to the petrochemical industry, which

now contributes some 85 percent of the Superfund. Other industries and the federal government contribute the remaining 15 percent.

The original Superfund act set up a panel composed of legal experts to study victim's compensation and make a report to Congress. The panel's report, which was released in September 1982, found that there are not enough effective legal remedies in our judicial system to compensate victims for injuries which may not become manifest until years after the victim was exposed to a toxic substance. The report recommended the establishment of a federally-managed, industry-financed fund to provide no-fault compensation for medical expenses and death benefits. Using the panel's findings, several members of Congress have now re-opened the victim's compensation issue.

Legislation to establish a federal victim's compensation trust fund has been introduced by Sen. Mitchell (D-ME), S. 945 and S. 946; Congressman LaFalce (F-NY), H.R. 2330 and H.R. 2482; and Sen. Stafford (R-VT), S. 917. The bills have many similar provisions, with the Mitchell and LaFalce bills setting three-year statutes of limitations on claims, and the Stafford bill setting a six-year statute of limitations. In addition, the Stafford bill, S. 917, deletes the Bevill amendment mining waste exclusions from Superfund.

Another bill, H.R. 2582, has been introduced by Congressmen Florio (D-NJ) and Markey (D-MA). While this proposal drops the establishment of a federal no-fault compensation trust fund, it contains provisions to make it easier for victims to win damages from the companies they sue in federal court. Congressman Markey may offer this bill as an amendment to the RCRA bill currently under consideration on the floor of the House.

SUPERFUND: PRESENT AND FUTURE FOR THE MINING INDUSTRY

by

Donald L. Ritter
U.S. Representative from Pennsylvania

Being a technical professional surrounded by attorneys in Washington, D.C. is sometimes a lonely vigil. There are three technical professionals and about 250 attorneys out of 435 congressmen in the system. Each has a different way of going about dealing with problems.

An engineer, a technical person, really looks to solve problems. An attorney looks to advocate one side or another of those problems, not necessarily solving it. An engineer tries to get all the information he can and takes a look at it to see if there is a possibility of getting the right answer or something that approaches the right answer. A good attorney gets all of the information that he can and then throws out that which doesn't agree with his position of advocacy.

It's a very different skill, and frankly, the U.S. Congress is woefully short of people who have technical backgrounds and it shows.

Many of you at this session are probably aware of how, on occasion, or perhaps frequently, badly it shows.

I think, by the way, having this convention here in San Francisco is symbolic. I mean, right in this area is the center of high tech; Silicon Valley is a stone's throw. And yet basic American heavy industry has got its convention here.

I am one of those people who firmly believes that in spite of the clamor and all the noise about high tech being the saviour of this country in terms of our economics, our basic industries had better well be part of the future of this country. Otherwise, we are going to be dealing with the impoverishment of America.

I serve as vice chairman of an 80-member Republican task force on high tech and high tech initiatives. It is interesting that my counterpart, the chairman, is a very bright young man out of Silicon Valley named Edwin Zschau, a freshman. He comes from Computerland, and I come from basic manufacturing America-land. I have a deeply labor dominated industrial district--first Republican in 50 years, and probably the only Republican in the House from such a district who thinks, talks and acts and votes the way I do.

Our view of high tech--and I have tried to bring this idea into the task force--is that our basic industries will use high tech, that a fantastic market for the high tech products are our basic industries, and that there are just so many home computers that are going to be out there.

The big systems and the high productivity systems--the sensors, the communications systems, the robots--all will be applied in the realm of basic manufacturing America and that will be the high tech revolution.

Obviously, these basic industries cannot be ignored as some of the philosophers from the social sciences, who never spent a day in their lives working in a basic industry, are pointing out. Neither can they be regulated out of existence. It would be a great tragedy if, through ignorance and fear and the lack of proper communication of difficult subject matter to the American people, we lost a goodly chunk of basic manufacturing America. It's not impossible.

The Superfund legislation is going to be reauthorized by 1985. How that reauthorization comes about will depend, to a great extent, on a far higher level of knowledge on the part of the American public on this subject of hazardous waste. It will depend to a great extent on a far greater effort on the part of people like yourselves to promote understanding and communication in this difficult field.

One great message that came out of the luncheon speech was if things are not going right according to what you think and you believe, your first amendment rights are there and you've got to speak up. If you don't speak up, the doomsayers and those who prosper on fear and ignorance will be victorious.

In the present situation, there is a good deal of confusion over just what constitutes a hazardous substance. There are a couple of conflicting definitions. One is a broad definition that says, for example, that a mining waste could be classified as a hazardous substance. That same definition says it is possible that a mining waste, even though it may contain elements or compounds that are classified hazardous, may not be finally adjudged to be a hazardous substance. Bill Hedeman from this panel has been personally active in opting for the broad decision.

It is, I think, positive for this industry and people who work for it that the EPA has taken a selective approach. A more restrictive view would be that, after all, these mining wastes do contain hazardous substances and therefore they should be classified as hazardous. Therefore, the accompanying rules and regulations of the law should be imposed.

Obviously you are familiar with some of the great differences between mining wastes and wastes generated, say, from the chemical industry. But the writers and the generators of the original law were not necessarily taking mining wastes into account, and that is why some of the confusion has resulted.

For instance, the volumes are quite different. An EPA generated Mitre study ranks potential hazard and talks about 10,000 drums as being an upper limit. As you know, 10,000 drums of waste material could be generated in an hour at some mining operations.

The study talks about 0.1 percent of heavy metal being the upper limit for heavy metal concentration, yet 0.1 percent is commonly included as a threshold limit and 0.1 percent is commonly available in mining wastes.

The question is, What does it mean? Is it, in that particular situation, dangerous? Is it really hazardous or is it to some extent insoluble? Is it stable? Does it work its way into the soil without getting into groundwaters?

These kinds of questions will be asked of you. If they are not asked, you should be presenting them and the answers to your representatives. Now is the time for people in this industry to take an active role with subcommittee members, committee members, and members of Congress in general so that there is no rush to judgment, so that there is no finale of crescendo one month final law writing, and all of a sudden everybody's trying to get their ideas across.

There is some time out there, and that time gives you an opportunity.

The question of certain new bills which impose a waste end tax is going to come up, and I am certain that there is going to be a good deal of congressional support for taxing the wastes generated as opposed to a particular feed stock.

Well, the kinds of wastes and the character of the wastes that are involved in mining have to be explained to the people involved in the legislative process. The impact on imports and the import sensitivity of the mining industry have to be explained to my colleagues.

I think that will give you opportunity to have some input.

There is good reason to believe that in and around the time of reauthorization of Superfund, the horror stories will start coming out and that the media will tend to look at the question from one side, which has happened not infrequently on this question of hazardous waste.

Again, you are going to find yourselves in a position of, in a sense, attack. I think the best defense is going to be a good offense. If you've got a case to make, you are going to have to make it. You are going to have to make it with the media, with the local politicians, with the state people, and with the federal people, because although Superfund is a federal issue, there will be great local pressure to tie up the various members of Congress and there will be much activism in the media.

I believe that it is possible to gain a better handle on this question of what is hazardous and what is not hazardous. It involves the assessment of risk and it involves putting that risk, once assessed, into some perspective for the public to understand in terms of what it does on an everyday basis, and I think we are going to come out ahead.

I know there is a lot of fear of laying this stuff on the line but, in my mind, after five years of being involved with these questions, the worst possible situation is rising out of ignorance.

I have had many experiences back in my own congressional district where the person on the street believes that we are drowning in a sea of chemical carcinogens and corporate America is getting away Scot free somehow, and if we don't do something about it real fast, you know, our kids, ourselves, our grandchildren, our heritage are in trouble.

That is more or less the present situation combined with the media looking for disaster and fear. Fear and disaster sells, along with white knight politicians in shining armor on grand steeds coming to save the people from the impending danger. These are the pitfalls out there, and I think much of what Superfund is going to turn into is going to depend on whether people like yourselves are out there in the trenches working, educating, communicating.

As I understand it, the question of hazardous and the definition of hazardous as defined by EPA relevant to the mining industry is not going to be settled as of October 1983, but there will be some delay, which means more and more that the next sets of changes will come with reauthorization of Superfund.

I would also like to point out there is a controversy, and many of you are aware of it, between the chemical industry and the mining industry over the potential of waste and legislation. I think the chemical industry doesn't want to see funds it contributed into Superfund go into massive projects to clean up certain mines.

I think people in the mining industry would be willing to fairly appropriate those funds once the hazard is judged to be significant and not unwilling to make their fair share of contribution.

By the way, on the significance of hazard, my bill H.R. 3840 has recently been reintroduced. This is on risk assessment research, demonstration and development projects, and it has the full support of the administration. It has six cosponsors including three leading Democrats on the Science and Technology Committee and three Republicans who are on both that committee and leaders in the technology field. I urge your support of that legislation as the alternative for intelligently assessing risk and involving the public in understanding the extent of the risk.

We are already spending hundreds of millions of dollars out of fear and ignorance and political realities that go with fear and ignorance. I am not blaming anybody, but we have got too much fear and ignorance right now.

You know, it is the ultimate dream of the Club of Rome promoters and the no-growth people--to cut off growth and cut off production and cut off economic activity that they view as the evil of modern technological society.

Think of it. It is one thing to tell the people we shouldn't produce, but it is another thing to tell people that this waste is bad, that anything we can do with it is insufficient, that its location near you is going to cause you serious and irreparable harm. At that point, things stop happening. There are certain spheres of this economy today which have already stopped producing because at some point, at some threshhold cost, production is not profitable. That is, at some threshhold cost of dealing with a waste problem, production is not possible.

You know, today people get away from the idea that production of wealth had something to do with natural resources. Somehow production of wealth is simply ethereal. Garbage. Absolute garbage.

Production of wealth is the use of all and each and every resource that a country has, and if we eliminate the basic natural resource production of this country, the prosperity will disappear. We are not Japanese. Nor are we about to be Japanese.

It is going to be a long time between simply importing feedstock and creating out of our wonderous brain power final products that will support the kind of lifestyle this country has. That Japan is going very well, thank you. But if you look at the way the average Japanese engineer and worker and middle management person lives, it is nowhere near the way we in this country live.

Think about it. Mining is one industry whereby with the vast millions, literally billions of tons of waste generated, if wrong moves are made in Washington, we could regulate you out of existence. We have already regulated several other

basic industries out of existence, or virtually so, such as the foundry industry. It could happen to mining.

As Reed Irvine says, there is nothing wrong with people like yourself exercising your first amendment rights and, as Superfund comes down the line, education of community people, politicians, media people, friends, neighbors, demonstrators, and the like, is going to be an essential ingredient to a--from your perspective--successful outcome.

SUPERFUND/RCRA: AN ENVIRONMENTAL JIGSAW

by

Louis J. Marucheau
Senior Environmental Attorney, Amax Environmental Services, Inc.

INTRODUCTION

Until not very long ago, solid waste management in the mining industry only concerned a few regulatory programs, such as applicable state mined land reclamation requirements and various types of land use controls. Although the federal government had established comprehensive programs regulating air and water discharges, it had no comparable program for solid waste.

This situation changed dramatically in 1976 when Congress passed the Resource Conservation and Recovery Act (RCRA) and the Surface Mining Reclamation and Control Act (SMCRA). While SMCRA was to have a profound impact on coal mining, it was the passage of RCRA that marked the beginning of full federal involvement in the regulation of solid waste.

Congressional concern with solid waste and its effect on the environment has increased over the years and led to enactment of additional laws, most notably the Comprehensive Environmental Response, Compensation, and Liability Act of 1980 (known as Superfund). Superfund established federal authority over any release of hazardous substances to the environment and imposed liability on persons associated with such releases.

The result is that federal laws such as RCRA and Superfund have tremendous legal and financial ramifications for the mining industry. To assess present impacts on the industry and to be able to anticipate and help frame future changes to these programs, it is necessary to understand the history of these programs, their general scope and content, and the way in which they deal with mining waste.

FEDERAL SOLID WASTE DISPOSAL ACT

Development of federal law regulating solid waste

In the United States, solid waste disposal, as typified by the city or county "dump," was long considered a matter of local concern. Consequently, early federal solid waste legislation (such as the Solid Waste Disposal Act of 1965) merely encouraged proper management of solid waste by the state. However, after continuing instances of environmental damage caused by improper solid waste handling and disposal, Congress concluded that more forceful legislation was required.

Passage of RCRA. By the fall of 1976, both the House and Senate had developed legislative proposals to completely rewrite the existing Solid Waste Disposal Act (SWDA) to create comprehensive solid waste management requirements (H.R. 14496 and S. 3622). However, the House bill was reported out of committee so late in the session that it was scheduled to be debated and voted on only four days before Congress was to adjourn for the November national elections.

Since there was no time to resolve differences between the two bills, staff members of the House Commerce Committee and the Senate Public Works Committee held meetings over the weekend (it is said in a Capitol Hill bar) and drafted a compromise bill. The following Monday a substitute bill (a 1-in. thick typed manuscript with handwritten notations) was introduced in the House, which quickly passed it without even having enough time to read the bill. The day before Congress adjourned, the Senate adopted the compromise bill, which was entitled the "Resource

Conservation and Recovery Act of 1976." RCRA became law when it was signed on Oct. 21, 1976.[1]

Post-RCRA amendments to the SWDA. As one might expect of a law hastily written over a weekend, a number of amendments have been made since 1976,[2] of which the most significant are the Solid Waste Disposal Act Amendments of 1980. The 1980 amendments expanded EPA's enforcement authority over hazardous waste but, at the same time, exempted from regulation certain categories of waste.

Congress, due to the requirement that the Solid Waste Disposal Act be reauthorized from time to time, is currently conducting a thorough review of the law. While legislation has yet to be finalized, it is clear from H.R. 2867 (which was reported to the floor of the House) and the latest Senate version that substantial amendments will be made by this Congress to the Solid Waste Disposal Act. These amendments will address, among other items of congressional concern, certain perceived "gaps" in the hazardous waste regulatory program, such as the small quantity generator exemption, exemption of burning of hazardous waste as fuel, and the lack of limitations on landfilling of hazardous waste.

Description of RCRA programs

RCRA completely rewrote the Solid Waste Disposal Act and established two separate programs for solid waste management--one for federally-designated "hazardous" waste; another for "non-hazardous" solid waste.

Hazardous waste program. For management of "hazardous" waste, Congress mandated a comprehensive "cradle-to-grave" regulatory program. The law requires federal standards for those who generate, transport, treat, store, or dispose of hazardous waste. In addition, permits are required for any owner or operator of a facility that treats, stores, or disposes of hazardous waste (known as TSD facilities). While individual states may administer this program, the state program must be "equivalent" to the federal program established by the U.S. Environmental Protection Agency (EPA).

The hazardous waste regulations promulgated by EPA may be found at the Code of Federal Regulations, Title 40, Parts 260-271. The regulations deal with general matters (Part 260), the identification of hazardous waste (Part 261), generator requirements (Part 262), transporter requirements (Part 263), requirements for permitted TSD facilities (Part 264), requirements for unpermitted TSD facilities which qualify for interim status (Part 265), temporary standards for permitted land disposal facilities (Part 267), permitting procedures (Part 270), and procedures for state assumption of the program (Part 271). Although these regulations are much too complex to be discussed in any detail here, several aspects of the program should be noted.

When assessing the impact of this program, one must look at each residual produced and how it is managed. EPA asserts authority over many industrial residuals not usually considered waste (e.g., "by products" which are sold). On the other hand, specific wastes (e.g., oil and gas wastes) and specific waste management practices (e.g., wastewater treatment units) may be exempt from regulation or subject to less onerous requirements. Only a thorough knowledge of these complicated regulations will enable one to properly determine the extent of their applicability.

Generators have limited requirements, such as reports and record keeping, but must ensure that all hazardous waste is sent with the proper manifest to facilities allowed to receive the residuals (authorized TSD or recycling facilities). Generators should, however, be careful not to accumulate hazardous wastes longer than authorized, lest they become a storage facility and thereby require a permit to legally operate. Since hazardous waste is considered a "hazardous material," transporters need do little more than follow the applicable Department of Transportation regulations.

In contrast to generators and transporters, the owners and operators of TSD facilities are subject to strict requirements. Besides a host of procedural requirements, including providing assurances of financial responsibility, these facilities must meet specified design and operating standards which are particularly stringent for surface impoundments, waste piles, land treatment facilities and landfills. For these types of facilities, there is a regulatory policy of total containment of the waste, which (subject to limited exceptions) results in requiring a liner, groundwater monitoring at the boundary of the waste management area, and corrective action if leachate exceeds specified concentration limits.

The hazardous waste regulations have been challenged by a large number of companies and trade associations, including the American Mining Congress, but the

issues have yet to be briefed and argued in court. Due in large part to the extensive settlement negotiations in this litigation that have been conducted since 1980, EPA has made numerous changes to the regulations. Further changes will undoubtedly be made, not only because of the litigation, but also due to adjustments by EPA after it has more experience with the program, due to future congressional directives, and due to possible expansion of the program to include currently exempt wastes.

Solid waste program. For "non-hazardous" solid waste, Congress used a more traditional incentive program to encourage the creation of effective state solid waste management plans. EPA was to promulgate guidelines for the development and implementation of state solid waste management plans. States were required to identify planning regions and agencies responsible for developing and implementing such plans, but they did not have to actually develop plans. Should a plan comply with the guidelines and be approved by EPA, the state would then be eligible for federal financial and technical assistance. EPA's guidelines are found at the Code of Federal Regulations, Title 40, Part 256.

The most controversial aspect of this program involves Sec. 4005 of the SWDA, which provides that any solid waste management practice constituting "open dumping" is "prohibited." Disposal practices constitute "open dumping" if the disposal site would not qualify as a "sanitary landfill" as defined by EPA-promulgated criteria. EPA's criteria for "sanitary landfills" (found at 40 CFR Part 257) may be difficult to meet because they require, in part, that leachate from the waste cannot cause drinking water standards to be exceeded in any groundwater beyond the solid waste boundary. The important legal issue concerning this provision is whether the prohibition can be directly enforced against the responsibile facility.

Because EPA's guidelines require the closure of "open dumps," it is clear that in states with EPA-approved solid waste management plans, citizens can require state agencies to enforce the prohibition. As for EPA enforcement, EPA contends that it has no authority to directly enforce the prohibition of "open dumping," but has stated that the prohibition is separate from the state planning process and can be directly enforced by citizen suit. Although there has been one federal court agreeing with this proposition,[3] a recent decision by another federal district court held, after a thorough review of the legislative history of RCRA, that the prohibition of "open dumping" has no effect apart from an EPA-approved state solid waste management plan. The court said that, even where such plan is approved, no citizen can directly enforce the prohibition against the facility.[4] While this 1983 decision is well reasoned, this issue will be open to litigation in other districts.

Application of RCRA programs to mining waste

Mining waste and the hazardous waste program. The Solid Waste Disposal Act Amendments of 1980 deferred regulation of certain wastes as "hazardous" wastes until at least six months after the submission to Congress by EPA of reports relating the results of studies of the exempted wastes. Among the wastes exempted are "solid waste from the extraction, beneficiation and processing of ores and minerals, including phosphate rock and overburden from the mining of uranium ore." This exemption, known as the "Bevill Amendment" after the representative who introduced it during floor debate on H.R. 3994, currently governs the applicability of the federal hazardous waste program to the mining industry.

In November 1980, EPA published an explanation of this exemption and so amended the hazardous waste regulations.[5] EPA stated that it would broadly interpret the amendments to exempt waste from the exploration, mining, milling, smelting and refining of ores and minerals (including coal). While EPA indicated that this exemption would include wastewater treatment sludges and air emission control dusts, it qualified the exemption by stating that it would not apply to wastes "not uniquely associated with these mining and allied processes," such as spent solvents and discarded commercial chemical products, and by further indicating that it fully intended to reconsider the scope of the exclusion.

The reports, which must be completed before EPA can regulate mining waste, are due to be submitted in October 1983. The EPA study of mining and milling waste (under Sec. 8003(f) of the SWDA) involved the assessment, including groundwater monitoring, of waste management practices at eight mining sites. This assessment, which was monitored by the American Mining Congress, has been submitted in draft form to EPA by its contractor, but it does not appear that the required report will be submitted on time. The study of mineral processing waste (under Sec. 8003(p) of the SWDA) has just been contracted by EPA and will be delayed even further than the mining and milling waste study.

There are some signs that the extent of the mining and mineral processing waste exemption is being called into question. EPA has given some recent indications that in the future it might determine that certain smelting and refining wastes may not be covered by the exemption. Also, although the legislative history of the "Bevill Amendment" appears quite clear that it was intended to cover smelting and refining wastes, there is a reference in the recently published House Report No. 98-198, Part 1, that indicates that current congressional staffers may not believe that all types of smelting waste are exempt. Only time will tell if the exemption will be modified.

Mining waste and the solid waste program. Presently, mining waste is subject to the "sanitary landfill" criteria, and certain mining disposal practices could be prohibited as "open dumping." When EPA promulgated its criteria for "sanitary landfills," the American Mining Congress sued EPA for improperly applying the criteria to mining waste. Although it appeared from the legislative history that Congress intended that the "sanitary landfill" criteria, as its name implies, was only intended to apply to municipal and industrial landfills, the United States Court of Appeals for the D.C. Circuit held that the "sanitary landfill" criteria applied to mining waste.[6]

Even though mining and milling waste disposal sites have not yet appeared on the inventory of "open dumps" published periodically by EPA, the possibility exists that they may be included and could be subject to closure, either under state laws passed to comply with EPA solid waste management plan guidelines or by citizen suit. Although EPA has yet to classify different wastes and develop specific criteria for each class, such separate criteria would be appropriate for mining waste and such classification is encouraged by the SWDA.

FEDERAL SUPERFUND

Development of the federal Superfund legislation

Although Congress believed that the passage of RCRA would result in proper management of hazardous waste in the future, there were growing concerns that past disposal practices had already caused severe adverse environmental effects. Cleanup of these sites was slow in coming because responsible parties could either not be found (so-called "orphaned or abandoned" sites) or were financially insolvent. Even if a solvent responsible party could be found, it was believed that cleanup could only be achieved through protracted and difficult litigation.

Consequently, in 1980 various bills were developed in both the House and Senate to create a fund to clean up hazardous waste sites and to impose liability for releases of hazardous substances into the environment. In September 1980, the House had passed two bills--H.R. 85, which established a fund and imposed liability for discharges of oil and hazardous substances to navigable waters, and H.R. 7020, which established a fund and imposed liability concerning inactive hazardous waste sites. By the time Congress recessed for the November national elections, a more stringent Senate bill (S. 1480), which had been reported out of the Senate Committee on Environment and Public Works in July 1980, had not yet reached the floor of the Senate.

When the 96th Congress reconvened after the elections to conduct the 1980 "lame duck" session, the Senate sponsors of S. 1480 encountered strong opposition to their bill and were forced to introduce a less stringent version on Nov. 18, 1980. However, due to continued opposition, the senators and their staffs quickly drafted a new compromise which was introduced on Nov. 24, 1980 and, after agreeing to limit amendments to a single amendment by Sen. Helms to stop collection of the fees for the fund after a certain date, was passed with virtually no debate.

In sending the bill to the House, the Senate leaders notified the House that any amendment, no matter how minor, would kill the bill if it was returned to the Senate. The House then considered the bill under a suspension of the rules and approved it on Dec. 3, 1980. On Dec. 11, 1980, outgoing President Jimmy Carter signed into law the Comprehensive Environmental Response, Compensation, and Liability Act of 1980. Thus, many provisions of Superfund are not addressed by either a committee report, a conference report, or floor debate.

There are currently several efforts to further amend Superfund. The compromise that removed those provisions imposing liability for injury to persons (Superfund only covers cleanup costs and damages to natural resources) also required a study to assess whether the present legal system adequately provided compensation to victims of exposure to toxic substances (the Sec. 301(3) study). In completing this study, a panel of 12 attorneys indicated that some compensation system was needed and recommended a two-tiered approach whereby victims could

receive administrative compensation (similar to workmen's compensation) and seek damages in the judicial system, modified somewhat to make recovery easier to achieve. This report may encourage a legislative response from congressmen, such as Sen. Mitchell who stated during the brief Superfund debate that "at least as to the Superfund, it's all right to kill people, but not trees."[7] In addition, there is an increasing belief in Congress that the present fund may not be adequate to clean up all the hazardous sites presently identified.

Description of Superfund program

Although Superfund is best known for its creation of a large fund to finance cleanup of hazardous substances from disposal sites (hence the name "Superfund"), the greatest impact of Superfund on industry is from its provisions dealing with actual and potential releases of hazardous substances into the environment. In order to encourage quick response to releases of hazardous substances into the environment and to inventory sites where such releases may have occurred, Superfund established certain notification requirements. First, any person in charge of a facility must report immediately to the National Response Center any release into the environment of a hazardous substance in excess of a designated reportable quantity, unless the release is federally permitted. Second, the owner or operator of any facility where hazardous waste was ever managed must have notified EPA by June 1981 of the existence of the site.

Having established procedures whereby government agencies are made aware of situations where hazardous substances may have been released into the environment, Superfund then provides authority for the government to respond to such releases. Whenever there is a release or threat of release of either a designated hazardous substance or, in the case of an imminent and substantial danger, a "pollutant or contaminant," the government has broad authority to take actions to clean up or otherwise mitigate the harm from such release, unless it is determined that a responsible party will properly carry out such action. Superfund provides for payment of government response costs, subject to certain limitations. One of the major limitations is that, for permanent cleanup actions, the site must be on the National Priorities List and the state must provide 10 percent of the cleanup costs and all future maintenance of the site.

In addition to authorizing government cleanup actions, the Superfund contains provisions facilitating government legal actions against parties responsible for the release. Where there is an imminent and substantial danger, the government can issue abatement orders to a responsible party, requiring him to take cleanup actions. Failure to comply with an abatement order can subject a party to treble damages in addition to the cleanup costs. Subject to a few limitations, Superfund also imposes, regardless of fault, liability for cleanup costs and damages to natural resources on (1) past and present owners or operators of sites where a release occurs, (2) generators who arranged for disposal of hazardous substances at the release site, and (3) transporters who selected the release site for disposal.

A major legal issue yet to be resolved is whether the liability imposed by Superfund is joint and several, i.e., whether each responsible party, regardless of the extent of his involvement with the site, is fully liable for all cleanup costs and damages to natural resources. Although one federal district court has held that non-negligent past generators are not subject to abatement orders,[8] the court indicated that the generators still would be liable for cleanup costs.

The heart of Superfund and the origin of its nickname is the provisions which established two massive funds. First, Superfund created a Hazardous Waste Response Trust Fund to provide a source of revenue to conduct cleanup activities where responsible parties were unknown or were unable or unwilling to conduct immediate cleanup. Claims against this fund may be made by any party carrying out cleanup actions in accordance with the National Contingency Plan and by state or federal governments for damages to natural resources. This fund is to be financed by federal appropriations (up to $220 million), by an environmental excise tax on certain chemicals, metals and oil (up to $1.38 billion), and by penalties collected from responsible parties.

Second, Superfund created a Post-Closure Liability Trust Fund to be financed from a tax on certain hazardous waste received at disposal sites after Sept. 30, 1983. All liability, whether under Superfund or "other law," arising from properly closed permitted hazardous waste disposal facilities is transferred to this fund. Congress believed that this would encourage siting of new hazardous waste disposal sites by providing a dedicated fund to take care of any problems which might develop after a site was closed.

Mining waste and the Superfund

When defining "hazardous substance" Congress referred to lists of substances identified under various federal laws and included hazardous waste, "but not including any waste the regulation of which under the Solid Waste Disposal Act has been suspended by Act of Congress." As described above, the Solid Waste Disposal Act Amendments of 1980 (passed less than two months before Superfund) exempted from regulation as hazardous waste, "solid waste from the extraction, beneficiation, and processing of ores and minerals." The legislative history makes it clear that exempted wastes are not considered "hazardous substances" even though they may contain substances designated elsewhere as hazardous.[9] To interpret the law otherwise would make all dirt and animal and vegetable matter "hazardous" because they contain small amounts of metals listed under the Clean Water Act because they are toxic in high concentrations. This issue is currently before the courts in litigation filed recently.[10]

Thus it would appear that mining and mineral processing wastes would not have much to do with Superfund. Such is not the case. While the government may only issue abatement orders for releases of hazardous substances, the government may take response actions for sites releasing "pollutants or contaminants," provided there is an imminent and substantial danger, and may, therefore, include them on the National Priorities List. When EPA formally proposed the National Priorities List, 17 of 418 sites were mining or mineral processing waste sites.[11] EPA has recently announced the addition of 133 sites to the list that, after other deletions and additions, result in a proposal for 539 sites, of which 22 are mining or mineral processing sites. Although sites may be listed, liability of responsible parties under Superfund only attaches to releases of "hazardous substances." Thus, while EPA may engage in response actions at such sites, the use of Superfund's special liability to recover cleanup costs may be restricted and the government may have to resort to other statutes or common law to recover.

In addition to being subject to Superfund response actions, mining industry facilities may also be subject to release notification requirements. Assuming EPA's current interpretation of the exemption for mining and mineral processing wastes is correct, releases such as spills of process chemicals or products such as sulfuric acid must be reported. Failure to report may result in criminal action against the person in charge of the facility.

CONCLUSION

To respond to perceived serious public health problems, Congress hastily enacted the two major laws affecting waste disposal--RCRA (which rewrote the federal Solid Waste Disposal Act) and Superfund. Mindful that the laws were intended to respond primarily to problems from past chemical waste disposal sites, Congress made some accommodation to certain types of low hazard, large volume waste such as that found in the mining industry. However, ambiguities in the program caused by the hasty enactment of the governing statutes and the desires of state agencies and EPA to address unresolved pollution problems, such as mine drainage, clearly indicate that the mining industry will, to some extent, be affected by these laws. Currently, the effect is limited primarily to (1) hazardous waste regulation of so-called non-indigenous waste, (2) potential future application of the "sanitary landfill" criteria, and (3) response actions under Superfund. However, litigation, further administrative action, or future amendments to the laws themselves may dramatically alter the current status.

EPA's MINE WASTE STUDY

by

Penelope Hansen
Manager, Analysis Assessment Program
Office of Solid Waste
Environmental Protection Agency

Mining wastes are one of the largest national waste streams. There is a lot of argument as to whether mining wastes or agricultural wastes are the nation's largest waste stream. It doesn't really matter which is because both are significantly large.

We think there are approximately 30 billion tons that are accumulated and also that about 2.3 billion tons additional are accumulated each year.

The Congress has had a great deal of interest in this subject in the last five years or so. The first two laws, SMCRA and UMTRCA as we call them, are aimed specifically at coal waste and uranium mill tailings waste, respectively.

The last two laws are the ones that have been under discussion so far this afternoon. The Resource Conservation and Recovery Act of 1976 mandated that the agency study mining waste. Basically it was large, its constituents were not well known, and the Congress said, "We want the agency to take a look at what's going on here."

That provision was in Sec. 8002(f) of RCRA. The Solid Waste Disposal Act amendments of 1980 added a new provision and that was Sec. 8002(p). This was basically another mining waste study. It is very similar to 8002(f).

The major difference is that 8002(p) has tied to it the exclusion from the hazardous waste regulations. The agency is precluded from regulating mining industry waste until six months after we complete our studies and submit a report to the Congress.

Clearly, 8002(p), then, focused very heavily on potentially hazardous wastes.

The congressional study calls for eight major points, which we have condensed into five here. We are to look at the source and volume of the wastes associated with the mining industry, we are to look at the current disposal practices and the alternatives to those disposal practices, and the costs for both present and perhaps alternative practices.

We are to look at the potential danger of both disposal and reuse of mining wastes, and to determine if any damages have taken place in the past.

The impact of the various disposal alternatives on the use of natural resources is one of the items that we have not looked at and that we will not be looking at until we determine whether the need for hazardous waste regulation is existent.

And finally, the current and potential uses of the waste--we have already completed that study, and we submitted it to the American Mining Congress and to the industry for review, I believe, about a year ago.

There are some segments of the mining industry that are not being addressed in this program. The first is the coal mining industry. The second is the uranium industry, because of the previously listed laws, which address those industries specifically.

We are not looking at oil shale because our study has been focused on active industries, and the oil shale industry is not what one would call active.

In situ mining we are also not looking at because that is covered by the Underground Injection Congrol Program at EPA.

Now, our study had basically three phases. The first thing we did was to characterize the waste streams from 600 sites. This resulted in the taking of approximately 400 waste samples and full-scale analysis of those samples.

Then, we selected sites for a year of monitoring and we selected eight sites. That was probably one of the most difficult things that we have had to do in this project.

Last but not least is Phase III, which is beginning now. We will do additional waste characterization sampling and analysis at 25 new sites, and we are also taking a look at contamination instances of the past which, as I had mentioned previously, is one of the line items that Congress required.

I would like to go through some of the data on our presurvey results, because clearly what's in a waste is very important to its definition as to whether it is defined in the legal sense as being a hazardous waste, or not being a hazardous waste.

Gold and silver. We took 14 tailings samples, which is by far the largest number of samples that we took for this particular industry. Gold was of particular concern because of cyanide and the cyanidization process. There is no primary drinking water standard for cyanide so we have expressed that in terms of a range, 0.6 to 41 ug/g (see fig. 1).

For the tailings pond liquid, of which we took six samples, we had cyanide that ranged from 12 to 76 mg/l.

There were a few samples also which exceeded for other things. There were three samples that were in the elevated range, which we define as being 20 to 99 times the primary drinking water standard, given the EP toxicity test.

For each of these parameters, there was one each, with the exception of the cadmium where there were two, that exceeded the 100 times drinking water standard.

Now, let me be very clear about this standard. EPA set up self-testing procedures for waste streams so that the regulated community could determine for themselves whether they had, by these test procedures, a hazardous waste. One hundred times the drinking water standard is that self-diagnostic, if you will, criteria. Between 20 and 100 is what we generally worry about as being an elevated range. This is considered to be a high range, and normally a clearly hazardous waste.

Now, mining wastes are, of course, excluded, so these are not hazardous wastes in the legal sense of the term now.

For the copper industry, probably the most interesting numbers are the ones for arsenic and lead from the leach liquors (see fig. 2). These numbers were a factor in deciding to evaluate this particular management practice for the copper industry.

There were two samples that exceeded 100 times drinking water standards. One exceeded 100 times drinking water standards for cadmium. Four of six samples exceeded the 100 times the drinking water standard for selenium.

In the lead-zinc industry, as one might expect, the parameters of concern were lead (see fig. 3). For the tailings of the 25 samples which we took, seven exceeded 20 times the drinking water standards, or were within that elevated range, and 5 exceeded 100 times the drinking water standard.

For moly, we had a couple of samples that were in the elevated range (fig. 4). None were in the high range, and we did show some cyanide ranges, but again, not very high for this industry. Obviously, much higher for the gold-silver industry.

In phosphate, there were a few elevated parameters, but we took many samples (fig. 5) and there were none that were in the high range.

For uranium, again, a large number of samples was taken--30 mine waste rock low grade ore (fig. 6). Again, tailings were considered here because (AMTRCA) handles that problem and we address only the non-tailings waste associated with the uranium industry.

We looked at iron and tungsten, taking 44 samples for those two industry segments, and basically found none that were either elevated or high for any RCRA parameter (fig. 7).

Fig. 8 shows the results from a study done by the Effluent Guidelines Division in which they took samples at mining sites for several industry segments and applied the RCRA testing procedure. Not quite as many samples were taken as we had for the other areas, but still a goodly number associated with these smaller industries in general. The only number that sort of jumps out at you is the 3 exceeding the 100 times drinking water standard of the eight associated with the antimony industry.

Another "contaminant of concern" that is associated with phosphate and uranium is radium 226 (see fig. 9 and 10). There is no RCRA standard for this, but clearly it is something that, at least in the literature, was an environmental concern when we began doing this study.

We have simply defined, to put it in a common context, elevated as being from 10 to 49 pico curies per gram and high as being over 50 pico curies per gram. There were none for phosphate. In general, I would say that the phosphate results turned out to be significantly lower in radium 226 than the literature at that time present would have led you to believe.

We have defined elevated in terms of a liquid sample as being between 100 pico curies per liter and roughly 500, and over 500 as being high; there was nothing in that range at all associated with phosphate. Even the number you might define as being elevated is comparatively small compared to the large number of samples that were taken.

Now, for uranium, there was a significantly larger number, as you might expect (fig. 10). Of the mine water samples, five of the eight exceeded, as far as pico curies per liter are concerned, the elevated definition. In solid uranium mine waste samples, 16 of the 30 samples were elevated. For the low grade ore, we have 11 of 13 in the high category and 6 of 12, roughly half for the mine water pond settled solids.

The next item that we come to, and this is a very brief summation, is how we selected sites for monitoring. To give you some idea of the magnitude of the difficulty here, it is generally conceded that there are somewhere between 12,000 and 20,000 mining disposal sites in the United States, active. Associated with the metal mining industry, there are somewhere between 5,000 and 6,000 sites.

Deciding which industry to focus on, and then getting down to the point of which sites to go to was clearly an intellecutal job of enormous proportion. I think to defend it, that we did it the only way we could. I will briefly run through the methodology that we used to select these sites. There is a much fuller explanation and a nice thick document that gives much more detail on how they were chosen. If you would like a copy of that, we can get it for you.

The first step was to determine which of the approximately 56 industry segments that are out there, which of those 56 we should focus on.

We took this first step prior to doing the pre-survey, before having the benefit of the data contained in fig. 1 to 10. This was based on literature, and we used two basic criteria. The first was size. Clearly Congress had set this industry aside primarily because of its gigantic size. The second one was waste characteristics, primarily toxicity, corrosivity and radioactivity.

The result of that step was to choose the copper, uranium, phosphate, lead, zinc, gold, silver, molybdenum, and iron industries to focus on as the major industries of our concern.

I think the justification is obvious there. For most of them it was size; for some it was toxicity and corrosivity; for two phosphate and uranium, radioactivity was also taken into consideration.

The second step was to determine which waste management practices and which wastes within those industries to monitor. Again, we chose size as our first major characteristic. Waste characteristics were the second. And the potential for transport, the particle size, and particularly the presence of water as a sort of a self-conducting medium was used in this step to determine which management practice to focus on.

After we decided which management practice to focus on, we then went to a substep, which was picking the major producing districts in which to pick our sites.

Of the various management practices that are present within the industries, there are two that are universal. Everyone has mine waste rock, overburden, etc. And everyone uses tailings ponds. Again, uranium was not considered applicable here but, of course, they have tailings ponds.

For other industries and other wastes, there were different kinds of management practices; for example, low grade ore dumps in copper and uranium. Almost unique to the phospahte industry are sand tailings piles.

So looking at the management practices and going through the criteria just mentioned, we basically chose these management practices to focus on and waste streams.

Of course, there are a lot of tailings ponds; we chose copper tailings ponds, phosphate, gold, silver and lead/zinc (fig. 11). We chose phosphate mine waste dumps primarily because of the radioactivity. And we chose leach dumps associated with the copper industry primarily because of toxicity. Mine water ponds for uranium, again, radioactivity.

This makes it sound like it was a very simple process. This was probably the most difficult step; that is, to make this cut and choose these wastes and practices to focus our research on.

We then did a series of maps, laying out where in the United States these industries were located, and what percentage of present production they represented. Fig. 12, for gold and silver, suggests that, if you were going to pick two states for study, you would probably pick South Dakota and Nevada, and that's what we picked. Some of them were not quite that clear.

Nonetheless, by laying all this out we came to our choices for tailings ponds with the copper industry as being Arizona and New Mexico and Utah (fig. 13). We were going to choose at least one site in those states. Same for the leach dumps.

For uranium, we had New Mexico and Wyoming for mine water ponds. For phosphate mine waste dumps, Idaho and Florida, and for phosphate tailings ponds, clearly Florida. That's where 90 some odd percent of the industry is located.

Having made those choices, we then went to Site Selection Step III (fig. 14).

Step III was fundamentally different from Step I and II. In Step I, we were trying to determine which part of the mining industry would be the most likely to have wastes that could impact the environment. Step II is to determine which waste management practices and specific wastes associated with those industries were the most likely to affect the environment. In Step III we specifically backed away from looking for the worst case actors, and we tried to find waste management practices that, based on our pre-survey data, were in the mid-range of toxicity or radioactivity or whatever the contaminant of concern was. Also, to find settings that were typical of the industry that we were trying to evaluate.

Last but not least were monitoring considerations; all sites associated with the mining industry are difficult in terms of interpreting the data simply because of their mammoth size. For some sites, it is probably impossible. And when sites came up in our typicality range that had particularly difficult topographies in terms of evaluating the data, those were rejected.

So we look for sites that were typical of the industries and practices we were trying to evaluate, and we did take into consideration the monitoring considerations and the monitoring complexities that we might see.

The sites selected, as given in fig. 15, are the botton line. I would like to take this opportunity to thank these companies who were very generous in their time and allowed us to put in monitoring wells and monitoring stations for both ground water and surface water.

Fig. 16, a schematic of the Fort Green site in Florida, gives an idea of the kind of monitoring done.

Shown are the disposal facilities, which are enormous impoundments, surface water monitoring stations (triangles on fig. 16), and each of the black dots represents a groundwater monitoring well. These kinds of schematics were done for all of the eight sites.

Our contractor, Pedco, has created reports on each one of these eight sites. Those reports have gone back to the industry, to the owners of these facilities for their comments, and we have received comments from three of the eight. We are waiting for the other five. We will modify our conclusions etc. based on those comments--those that we take to be valid, clearly. We will then distribute for peer review a three-volume report on this $2.8 million study. We have asked the American Mining Congress to be one of those peer reviewers, and they have accepted. Those reports should be out next month.

But let me give you a few sort of bottom line preliminary findings if you can have such a thing. These are preliminary in that, as I said, we have not received the comments back from most of the facilities, and we intend to take those comments very seriously. But in general, this is what I think we can say are legitimate preliminary findings.

First, surface water was not apparently impacted at any of the sites that we monitored. That is a rather significant finding.

Radioactivity is apparently not impacting ground to surface water at either the uranium mine water ponds or at the phosphate site. The most pressing concern for both those industry segments is radioactivity, and it does not appear to be reaching groundwater--at least, not at the present time.

There was evidence of seepage at all of the impoundments that we monitored. I think that is more or less to be expected. Clearly, impoundments carry their own mode of transportation in that they do have a constant head. They are covered with water, and as a consequence, I don't think that is a surprising conclusion.

The next one is not a surprising conclusion either; hydrologists and geologists know it to be true, and this study which we have conducted is one of many that confirms that the local hydrology controls the rate of seepage, and the local geochemistry controls the extent of the contaminants, how far they move into the environment and at what concentration.

We evaluated seepage collection systems--two or three varieties. We found that if they are properly installed and operated, they can be a very effective mitigative control for keeping pollutants from ground water.

Last but not least is another fact that was confirmed: acidic wastes and/or environments significantly increase the probability of groundwater contamination.

As I said before, we are going into another phase of this study. We are going to be reviewing state files as the Congress directs us in the study to determine instances of contamination and instances of releases of pollutants to the environment from mining waste.

We are going to be reviewing the Superfund data, and this is supposed to take place over the next six months. We had the kick-off meeting last week. It is conceivable that we should get that work done by March 1984.

In addition, we have done a statistical analysis of the waste characterization data that we have on the various segments of the mining industry. We have determined that we are deficient in having enough samples for some of the industry segments, which we intend to address in our report to Congress.

Our report to Congress, which I expect to be there this time next year, will not address the entire mining industry. We hope to address all of the metal mining segments and phosphate and asbestos.

We then hope to begin a new study, although probably not as exhaustive as this study has been, of the nonmetal mining industry other than phosphate and asbestos.

The 25 sites as selected in phase III of our study and 125 samples will be taken over the next six months. You may be contacted by our contractors. We have two working with us on this particular phase--a contractor from Cambridge, and Pedco again will be participating in this part of the study. With these additional

25 sites, we hope we will have a statistical representation of all of the wastes associated with the metal mining industry, phosphate and asbestos.

Now I would like to clarify, particularly in the context of the previous speakers, the options for mining waste regulation under the present law.

First, if any of the mining wastes are determined to be hazardous, any of them, we have two choices. We can either apply the full range of the Subtitle C standards as they exist today, the hazardous waste regulations as they exist today, or we can propose in the Federal Register and hopefully promulgate at some point waste specific, but still mandatory, standards under Part 266.

Part 266 is a piece of the regulation that has been saved for special kinds of problem wastes that don't fit into the normal structure of hazardous wastes. Just to give you an example of that, waste oil will have its own 266 regulations because that is a waste stream that just doesn't fit into the normal ebb and flow of hazardous waste as we commonly think of it.

I have always felt that if we determined that any of the wastes that we have studied are hazardous wastes and need not the full, but Subtitle C control, national hazardous waste control, that in all probability Part 266 regulations would be the route that we would take.

If and I shouldn't say if, because right now all mining wastes are in this category, and once we send our report to Congress, if we determine that only a few of the mining wastes need to be controlled as hazardous wastes--a few or none, I should certainly add the caveat "or none"--then all mining wastes would be in the second column of fig. 18. They would be nonhazardous wastes by the meaning of the law.

I would like to stress as a personal observation that the terms hazardous and nonhazardous have been one of the greatest problems with RCRA and probably with Superfund as well. If you open a pop-top can, drop it on a beach and I step on it, that to me is a hazardous waste. What we are talking about is the continuum of risk, starting with probably the first one that comes to mind--say dioxin--and moving all the way through to that innocuous little pop-top. But it depends on where it is and what is done with it as to how "hazardous" it is.

Nonetheless, this is the legal framework that we must deal with and, therefore, according to RCRA, it has to go into one category or the other.

So getting back to the nonhazardous category, if we took no action, then the wastes would stay as they are today in the nonhazardous category controlled by the Subtitle D land disposal criteria, subject to the open dump inventory, with the states bearing fully implementation and responsibility.

Or, and again there is a high probability that this will happen, we can write waste specific advisory guidelines to the states based on this research, telling them what we found and what we think are the best management practices for mining wastes.

It is conceivable that we could end up in a situation where we have some mining wastes in all four of these, because clearly mining wastes are not monolithic. They differ widely in their chemical and physical characteristics and they certainly differ enormously in their size, which I believe is really what got them the special distinction to begin with.

Nonetheless, these are the four options--legally, I think there are no others. Mining wastes, all mining wastes, will end up in one of these four categories.

It is important for the agency to determine which category they want them in, but it is also very important to get input from the industry as to which category you think they belong in.

SUPERFUND—MINING SITES ON THE NATIONAL PRIORITIES LIST

by
Brian L. Murphy
Senior Consulting Scientist

William W. Beck, Jr.
Principal Consulting Geologist
and
Dennis F. Unites
TRC Environmental Consultants, Inc.

On December 20, 1982, 418 sites were placed on the National Priorities List (NPL). (Times Beach, Mo. has since become the 419th site and further additions to the list are expected on about Aug. 1, 1983.) This was the culmination of an effort by the Environmental Protection Agency and numerous state agencies to identify the hazardous waste disposal sites in the United States which present the greatest risk to human health and/or the environment.

Sites believed to present a hazardous waste problem are designated for the NPL by a two-step procedure:

1) The states nominate sites for the NPL. Under the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), which established this procedure, each state must have at least one site on the NPL.

2) An intendedly objective scoring system developed by the Mitre Corp. for EPA (the "Mitre model") is then used to select sites. Mitre model scores are furnished by the states with their nomination. In reality, EPA or EPA contractors did the scoring for the states in many cases.

EPA has estimated that there may be 10,000 to 20,000 hazardous waste sites potentially covered by CERCLA. Of these, 690, or about 5 percent, were nominated for the NPL. Thus, the winnowing process in Step 1 is much greater than in Step 2 (418/690 = 61 percent). For mining sites, 31 locations were nominated, of which 17 sites were selected. Presumably, like the other sites, the mining sites nominated represent only a small fraction of the total population.

The second step of the listing process is the comparison of Mitre model scores to compose the NPL. The model calculates scores for five "pathways" of potential human exposure: ground water, surface water, air, direct contact, and fire and explosion. The first three pathways are combined (by taking the square root of the sum of the squares) into an overall "migration" score. The migration score is essentially the determinant for listing on the NPL. According to the National Contingency Plan (47 FR, 137, 31180, July 16, 1982), placement of sites on the NPL is based primarily on the migration score. The fire and explosion and direct contact score may be used to determine if emergency attention is needed.

The score for each of the three migration pathways is the product of scores for three "factors":

1) The existence or likelihood of a release. An "observed release" which is basically a measurement of concentration above background at any location automatically produces the maximum score.

2) A "characteristics" score, which is the sum of scores for quantity and toxicity/persistence for water pathways and quantity, toxicity and reactivity, and incompatibility for the air pathway. The score for "quantity" is determined by the total volume of waste while the score for parameters like "toxicity/persistence" is determined by the most toxic and persistent component.

3) Characteristics of the population or sensitive environment at risk such as distance to point of exposure and number of people involved. Potential scores for population factors are much larger than for purely environmental factors.

In this paper, mining sites are defined by whether the practices at the site would qualify an operator for membership in the American Mining Congress. These practices include extraction, smelting, and refining but not fabrication into a final product. Only sites where mining practices are responsible for most of the Mitre model score are analyzed. Under these criteria, the 31 mining sites analyzed, including 17 NPL sites, are shown in table 1.

This paper is concerned solely with the technical validity of the listing process. Legal issues, such as the propriety of including mining sites in Superfund, are not considered. Nor are site-by-site characterizations a primary concern; this is done only to the extent necessary to provide perspective on the validity of the Mitre model results.

NOMINATION OF SITES BASED ON EXTENT OF EXISTING INFORMATION

In generating Mitre model scores to be submitted for a site's nomination, a general result is: the more information available, the higher the score. This result is as true for sites not causing any signficant harm to the environment as it is for genuine problem sites.

The Mitre model score rises with the available information for the following reasons. The instructions for using the model specify that where there is no data for a factor, it is assigned a value of zero. Further, where data is lacking for two or more factors, the entire pathway score (air, ground water, or surface water) is set to zero. Finally, the maximum score for any pathway can only occur for a measurement, or other conclusive evidence, of a concentration above background (irrespective of whether the concentration is significant in terms of health standards and criteria).

Most of the 31 mining sites nominated for NPL have prior studies; some have a history of EPA and/or state negotiations and in a few cases consent decrees. Further evidence that these sites are well known is the fact that all of the 17 NPL sites and 10 of the 14 additional sites have "observed" (that is, measured) releases in some route category. Although a site may be well known for some environmental impact, it may not be in an area scored by the Mitre model. For mining sites, for example, acid mine drainage and its effect on aquatic life are often of concern; this is the case at 8 of the 17 NPL sites. No score is given for acidity in the Mitre model.

The following table shows which routes contributed to scoring at the 31 sites.

Mitre Model Scoring

	Air (%)	Ground Water (%)	Surface Water (%)
NPL Sites (17)			
Considered	41	94	88
Highest Score	18	65	18
Non-NPL Sites (14)			
Considered	0	100	100
Highest Score	0	71	29

Unlike ground water and surface water, the air route only contributes when there is a measured release (rather than a likely release). The reason the air pathway does not occur for the non-NPL sites is that they generally do not have as extensive measurements as the NPL sites. Almost all mining sites consider both ground water and surface water pathways in the scoring with the highest scores generally being obtained for the ground water.

Overall structure of the model in combining source, release and population information is shown in fig. 1. Note that,as illustrated, the information required is designed to be readily available rather than self consistent.

To gain some insight into what distinguishes the NPL from the non-NPL sites, a sensitivity analysis was performed for each parameter occurring in each pathway score. This was done by decreasing each parameter score by 50 percent and calculating the overall change in the total score. An example will make this procedure clearer. At the first entry in table 1, the Anaconda smelter site in Anaconda, Mont. the total migration score is 58.7. In obtaining this result, "quantity of waste" in the ground water pathway was scored as 8 points. Had quantity of waste

been scored as 4 points the migration score would drop by 6.0 points to 52.7. For the parameter "toxicity/persistence" in the surface water pathway, a score of 18 was recorded. Had this score recorded as 9 points, the migration score would drop by 2.7 points to 56.0. Hence the overall score is more sensitive to the value of the first parameter. Table 2 shows the results when all pathways are combined so that "observed release" represents any of the three pathways, etc. The different pathways were combined because they basically all behave the same way. Numbers in table 2 may add to more than 17 horizontally, because more than one pathway is considered.

The fact that the maximum number of sites occurs along the diagonal in table 2 indicates a consistent pattern of parameter importance. Whether or not there is an observed release is almost always (16 times out of 17) the most important factor; population factors and distance to well or intake are usually the second most important factor and so on.

This picture of how the Mitre model works can be simplified even further by just considering the top four parameters in table 2 and recognizing that for parameters such as distance to well/population served or distance to stream/population, the population portion of the parameter is a good indicator of this whole factor (of course, it is the whole factor for the air pathway) since people require wells or surface water. The population figure used is the figure mentioned in scoring that pathway at that site.

Results are shown in the following table for the rule: "Observed release, population greater than 100 and (near) maximum toxicity, persistence, and quantity in any one pathway produces an NPL site--failure to satisfy these conditions does not":

Percentage of sites satisfying the selection rule

NPL site*	94%	(One site not an observed release, 16 satisfy the rule)
Non-NPL sites	6%	(13 sites satisfy the rule, one does not)

* One NPL site has next to maximum score in the dominant pathway for the toxicity/persistence parameter. Score in this pathway is based on copper rather than cadmium, which was used in the other pathway and which would have produced a maximum score. All the others score the maximum in these categories.

The two sites not satisfying this rule are of particular interest. Alden mill has the highest score of any non-NPL site, higher in fact than several of the NPL sites, but it is based on "unproven" arsenic content of the waste. This may be why it is an exception to the selection rule and was not listed. The NPL site not satisfying the rule is Celtor Chemical. It scores maximum on toxicity, persistence, quantity and has a population nearby of more than 100, but it is an inferred rather than an observed release. It has the second lowest score (the lowest scoring NPL site is the Mountain View Mobile Homes asbestos site) of the NPL sites and in fact is lower than the score for Alden mill. The Celtor Chemical site scores fairly high on direct contact, however, and is said to be a children's play area on the Hoopa Indian Reservation. Although the direct contact hazard to children does not enter into the migration score calculation, it may be the reason why this site is an exception to the selection rule.

MINING SITE CHARACTERISTICS LEADING TO LISTING

In summary, the way the Mitre model treats mining sites can be represented by the equation:

Mitre Model Score	=	Observed Release Score	x	Quantity Toxicity, Persistence Score	x	Population Score

As illustrated in fig. 2:

- Mining sites almost automatically receive the maximum quantity, toxicity, persistence score based on total amount of tailings, spoils, slag or discharge and on the presence of small amounts (relative to bulk waste) of metals, etc. Of the 31 sites, 26 had maximum or next-to-maximum scores in some pathway for this factor.

- A mining site which is nominated for the NPL will tend to have maximum score for an "observed release" in at least one pathway (27 of the 31 did) because only sites that have been previously studied tend to be nominated and any concentration measurement above background (no matter how small) constitutes an observed release.

- With maximum scores in these two areas, the total score will be high enough for listing on the NPL unless there are virtually no people in the area. Twenty-five out of 31 sites had more than 100 people within three or four miles.

WHY 14 SITES WERE NOT LISTED

Table 3 presents the specific reasons, in terms of the three factors comprising the rule, why the 14 non-NPL sites failed to score high enough for listing. Results are given only for the highest scoring pathway.

Lack of an observed release and little or no population nearby are the most common reasons for low scores. Of the five cases where quantity and toxicity/persistence scores were not (near) maximum, two of the sites were tram sites and the quantity of waste is actually relatively small. At another two of the five sites, the toxicity and persistence scores were based on sulfuric acid and cyanide rather than trace metals in the waste. Had the scorer selected metals, maximum toxicity/persistence scores would have been achieved.

VALIDITY OF MODEL APPLICATION TO MINING

After reviewing the 31 sites nominated for the National Priorities List, the authors of this paper are convinced that what distinguishes NPL sites from non-NPL sites is not primarily degree of hazard. Rather, the distinction is based mainly on how much prior study has been done at a site and how rural the surroundings are. It could be argued that both of these factors correlate to some extent with degree of hazard. This is true, but the model then must be viewed as assessing risk in an extremely indirect way.

As has been noted, special characteristics of mining sites that contribute to high Mitre model scores are the large amounts of waste involved and the presence of trace metals in the waste. These characteristics tend to produce maximum scores in one of the three scoring areas--ground water, surface water or air. Thus, scores in the other two areas that are too small to produce listing at a chemical dump may be sufficient to list a mining site.

It is concluded that the Mitre model is not a useful tool for assessing or ranking hazards at mining sites because the score is produced by factors which have little to do with the actual hazards at the site. The Mitre model seems to have been developed with chemical dumps in mind. In that context, its scoring system may be more useful. For example, maximum quantity of waste may indicate more than 10,000 drums of chemical present rather than, as for mining, more than 2500 tons of spoils, slag or tailings. Maximum toxicity at a chemical dump may indicate presence in concentrated form of very toxic or carcinogenic compounds rather than, as at many mining sites, the normal or unconcentrated elements in the earth at the site.

Figure 1. Overview: Mitre Model Methodology

Figure 2. National Priorities List (NPL) Overview: Mitre Model Logic

TABLE 1

SITES ANALYZED

NPL Sites	Mining Activity[2]
1. Anaconda Smelter Anaconda, MT	Copper smelter
2. Bunker Hill Smelter Smelterville, ID	Lead and zinc smelter
3. California Gulch Leadville, CO	Metal mines
4. Celtor Chemical Humboldt County, CA	Metals reclamation mill
5. Central City - Idaho Springs Clear Creek and Gilpin Countries, CO	Gold mines
6. Commencement Bay Tacoma, WA	Metal smelting
7. Homestake Mining Milan, NM	Uranium mill
8. Iron Mountain Mine Shasta County, CA	Copper mines
9. Millitown Reservoir Millitown, MO	Copper mines and smelter
10. Mountain View Mobile Homes Globe, AZ	Asbestos mills
11. Palmerton Zinc Palmerton, PA	Zinc refinery and smelter
12. Silver Bow Creek Silver Bow and Deerlodge Counties, MT	Metal mines and mill
13. Tar Creek - Kansas Cherokee County, OK	Lead and zinc mines
14. Tar Creek - Oklahoma Ottawa County, OK	Iron and zinc mines
15. United Nuclear Churchrock, NM	Uranium mill
16. U.S. Titanium Nelson County, VA	Mine and refinery
17. Whitewood Creek Black Hills, SD	Gold mines and mill
Recommended by States but Not NPL Sites	
18. Alder Mill Twisp, WA	Metals mill
19. Anaconda Copper Weed Hts, NV	Copper mine
20. Anaconda Refinery Great Falls, MT	Copper and zinc refinery
21. ASARCO Globe Facility Commerce City, CO	Metal recovery (smelting)
22. Blackbird Mine Cobalt, ID	Mine
23. Gateway Mill site Gateway, CO	Vanadium mill
24. Hendricks Mine Boulder, CO	Radium and fluorspar mill
25. Golden Mine Golden Village, WA	Metals mine
26. Loma Mill Loma, CO	Vanadium mill
27. Placerville Tram Placerville, CO	Vanadium tram/ore bin
28. Rio Tinto Mountain City, NV	Copper mine
29. Sawpit Tram Sawpit, CO	Vanadium tram/ore bin
30. Silver Mountain Mine Loman, WA	Gold and silver mine
31. Vanadium Mill Site Vanadium, CO	Vanadium mill

2 This is the mining activity mainly responsible for the Matrix Model score. At some sites, non-mining uses also contribute to the score. At other sites, the use has now changed from that listed.

CHAPTER 8

DEVELOPING A COOPERATIVE APPROACH TO ENVIRONMENTAL REGULATION

In the past in the U.S.A., when a representative of the environment protection agency introduced the purpose of his visit as, "I am here to help you," this invariably led to a series of problems and new cost items for the operator of a mine or mill. This happened so often that the EPA man's, "I am here to help you," has become ingrained in the joke about the three most commonly used lies.

When a mining company opens its doors to the EPA, the information gained by the regulator may result in more expense and problems for that company. The older generation of senior mining company management has pretended for so long that if one ignores the problems presented by regulators, they will go away.

Consequently, since the mining industry was not exactly forthcoming in helping regulators develop the means to cause them grief, the regulatory movement had to develop its own information and effluent treatment technology. When regulations based on this technology were imposed on industry, industry lawyers emphatically claimed that the rules and technology for treatment requirements imposed were out of context.

Mining companies and the American mining industry through the American Mining Congress has sued the EPA many times over proposed or promulgated regulations. The EPA and state governments have and are suing numerous mining companies over environmental damage at their operations. Throughout all this, private environmental organizations have become intertwined in the action suing both the EPA and the mining companies who have involved themselves by voicing objections at virtually every public hearing held to discuss a mining company permit application or proposed new regulation.

The result, in the U.S.A. at least, is a degree of bitterness and a general spirit of mistrust and confrontation between mining companies, regulators, and environmental groups. Even within the mammoth regulatory bureaucracies, there is a well-ingrained hierarchy in each division and group and some degree of mistrust between one bureaucratic group and another, or between the regional offices and Washington, or one branch of government and another, as each possessively guards its area of jurisdiction or invades for that of another. The result is not constructive and does not serve the environment, the people, or the mining industry's best interests.

It is high time to spend whats left of shrinking resources available on the environment itself rather than on supporting huge hierarchial bureaucracies with overlapping responsibilities, especially rather than on litigation and lawyers.

All groups need to find some common ground and work together toward the common goal of minimizing, as far as cost effective, the impact of mining and mineral processing on the environment.

In this context, the following paper by EDELMAN and WALLINE (1982) is refreshing and deserves a chapter on its own in this report.

LAURENCE H. EDELMAN*
ROBERT E. WALLINE†

Developing a Cooperative Approach to Environmental Regulation[1]

Amidst charges and counter-charges concerning the efficacy of the United States Environmental Protection Agency's (EPA's) enforcement efforts, it is all too easy to lose sight of the real issue, environmental results. While the rhetoric often centers on numbers of enforcement cases filed and amounts of fines collected, from a technical viewpoint, a better measure of effectiveness is the number of environmental problems solved and the degree of positive environmental benefits achieved.

The case of *U.S. v. Homestake Mining Company*[2] is illustrative of the potential benefits to be derived from developing a cooperative approach to solving an environmental problem. This article traces the history of the Homestake case from its genesis as an EPA enforcement action, through a confrontational litigative phase involving eight separate civil proceedings, to its resolution in an innovative Consent Decree that holds the promise for development by Homestake of a state-of-the-art water pollution treatment system.

I. HISTORICAL BACKGROUND

The Black Hills of South Dakota is an area rich in mining history. Though overshadowed by tales of the California Gold Rush, the 1874–79 rush in the Black Hills was proportionately of equal magnitude.[3] Spurred by reports of the Custer expedition's gold discoveries in 1874, miners flocked to the Central and Northern Black Hills locating placer claims on the streams, and later, staking out lode claims seeking the gold ore from which the placer deposits had originated.

In 1876 an outcrop of gold ore, Homestake Lead, was discovered in an

The views expressed herein are those of the authors and do not necessarily represent those of EPA.

[2]Civ. No. 78-5094 (D.S.D. 1978).

[3]The colorful history of South Dakota's gold rush and the Homestake mine is portrayed in PARKER, GOLD IN THE BLACK HILLS, University of Oklahoma Press (1966), and DEADWOOD: THE GOLDEN YEARS, University of Nebraska Press (1981).

area now encompassed by the town of Lead, South Dakota. By 1877 the Homestake Mining Company had been incorporated by California investors led by George Hearst, and the Homestake was to become the financial foundation of the Hearst publishing empire.

Early mining at Homestake was done on the surface in open cuts, but underground mining followed closely. On-site milling began in 1878 with the use of stamp mills. Gradually, the Homestake mine and mill complex expanded and modernized, becoming what is today the largest gold-producing facility in the Western Hemisphere.

Mineral development in the Black Hills was not without significant environmental impacts. The smaller mining operations resulted in erosion and leaching of metals into the streams and rivers. Homestake, following the traditional mining practice, discharged its untreated mining and milling wastes directly into Gold Run Creek, a tributary of Whitewood Creek and the Cheyenne River drainage. In 1881 the Territory of Dakota recognized by law the local customs providing for use of streams for mining and milling purposes, including waste disposal. Later, Whitewood Creek was classified for industrial waste disposal pursuant to South Dakota state law.[4] One historical account of the environmental impact created by the Black Hills mining rush contains this vivid description:

> The pollution produced by the Homestake—and indeed by all of the mines—first stained the creek waters red from the cement ores and placers, then grey with the slimes of the mills, and the reek of cyanide hung over the valleys of Deadwood and the Whitewood like a curse.[5]

Not only did Whitewood Creek bear the impact of Homestake's effluent, but the towns of Lead and Deadwood also discharged their raw sewage to the creek. By 1976 the use of Whitewood Creek as an open sewer for mill tailings, toxic chemicals, and municipal waste had become a one hundred year tradition.[6] Even the oldest citizens of the area could not recall a time when the stream had supported aquatic life.

II. BREAKING WITH MINING TRADITION—IMPACT OF THE FEDERAL WATER POLLUTION CONTROL ACT

During the 1960s general public awareness of environmental issues heightened. This new environmental consciousness and desire for environmental quality spread west to confront the time-honored traditions of the

[4]South Dakota 1935 Session Laws, chapter 174 § 4; SDCL 46-25-5 (1967).

[5]PARKER, DEADWOOD: THE GOLDEN YEARS, *supra* note 3 at 112.

[6]In November, 1981 South Dakota nominated a portion of Whitewood Creek as its number one priority for investigation under the Comprehensive Environmental Response, Compensation, and Liability Act, 42 U.S.C. 9601 (Superfund). In August, 1982 EPA, Homestake and South Dakota entered into a voluntary agreement to study the potential hazardous environmental effects of the tailings historically deposited in and along the stream.

miners. By the mid-1950s there appeared to be a general consensus among the Lead-Deadwood locals that the discharge of Homestake's untreated mining wastes and the raw municipal sewage to Whitewood Creek was unacceptable. Discussions among local, state, federal, and company officials concerning the Whitewood Creek water pollution problem, took place throughout this period but no remedial actions resulted.

Not until passage of the 1972 Federal Water Pollution Control Act Amendments (FWPCA) was a regulatory process established that would change past practices.[7]

The National Pollutant Discharge Elimination System (NPDES) permit program created in section 402 of the FWPCA[8] required Homestake, for the first time, to obtain a federally enforceable permit for the discharge from its operations. Moreover, by the July 1, 1977, statutory deadline, Homestake's discharge was to meet effluent limitations derived from the technology-based guidelines set by EPA, as well as potentially more stringent water quality standards based on classification of Whitewood Creek as a fishery by South Dakota in accordance with section 303 of the FWPCA.[9]

Homestake's NPDES permit was issued by EPA on September 3, 1976. The permit established effluent limitations for total suspended solids, cyanide (which is present in the discharge because of the use of a cyanidation milling process), and heavy metals and incorporated the July 1, 1977, compliance date of the FWPCA.

For Homestake attaining compliance with the requirements of the FWPCA would prove no small task. Elimination of the mill tailings discharge necessitated construction of a major $25 million tailings impoundment in Grizzly Gulch. In addition to eliminating the tailings discharge, a final treatment system for suspended solids, cyanide, and heavy metals was necessary to treat the remaining wastewater discharge. Given the magnitude of such an undertaking, Homestake, like many major industrial dischargers, did not meet the July 1, 1977, FWPCA deadlines.

In late 1977, EPA and Homestake entered into a Consent Decree and Stipulation, *U.S. v. Homestake Mining Company*,[10] that allowed Homestake a time extension to complete its tailings impoundment by December 1977 and the necessary treatment system by April, 1978. Homestake completed the multimillion dollar tailings pond on schedule and began diverting the tailings discharge to Grizzly Gulch.

[7] 33 U.S.C. 1251 *et seq.* (1976) The FWPCA was significantly amended in 1977 by Pub. L. No. 95-217, 91 Stat. 1566 (1977) and is now commonly referred to as the Clean Water Act.

[8] *Id.* at § 1342.

[9] The FWPCA also forced construction of a municipal wastewater treatment system for Lead-Deadwood.

For detailed judicial summary of the FWPCA's regulatory provisions and the interrelationship between technology-based limitations and state water quality standards, *see* EPA v. California *ex rel.* State Water Resources Control Board, 426 U.S. 200 (1976); United States Steel Corp. v. Train, 556 F.2d 822 (1977).

[10] Civ. No. 78-5002 (D.S.D. 1977).

The treatment system, however, was another story. Homestake's traditional mode of operation with its emphasis on production provided a minimum of staff for pollution control. The design of the original treatment system was attempted by Homestake production staff who drastically underestimated the complexity of the wastewater treatment problem. Reality became painfully clear when the ozonation unit, which Homestake initially installed for cyanide destruction, actually resulted in more cyanide in the effluent than was going into it in the untreated wastewater.

With the dismal failure of its treatment system Homestake was in violation of the Consent Decree and faced not only stipulated penalties, but also fines for violations of permit limits on expiration of the Decree. Homestake, therefore, requested that EPA modify its permit to relax critical limitations and subsequently also moved the district court for relief from the Decree, touching off what was to become a Donnybrook of litigation involving EPA, Homestake, and South Dakota.

III. FROM LEGAL CONFRONTATION TO TECHNICAL COOPERATION.

EPA denied Homestake's NPDES permit-modification request on the basis that Homestake had not shown any new evidence supporting a modification. Homestake petitioned the court of appeals for review of EPA's decision, but that petition was subsequently dismissed as time-barred.[11]

Meanwhile, the federal district court had granted Homestake's motion for relief from the Consent Decree under Rule 60(b) of the Federal Rules of Civil Procedure. EPA responded by appealing the court's ruling, and later filing a separate civil enforcement action in the district court, for penalties and injunctive relief based on Homestake's continuing NPDES permit violations after the Consent Decree had expired on July 1, 1978.[12] South Dakota intervened as plaintiff. Homestake countered by challenging EPA's approval of South Dakota's water quality standards and by directly challenging the South Dakota standards in state court.[13]

[11] Homestake Mining Company v. EPA, 584 F.2d 862 (8th Cir. 1978). The court refused to address either the merits of Homestake's petition or EPA's position that its denial of the permit modification request was unreviewable. The court found that Homestake's petition was four days late, even when calculated from the date of EPA's denial, and, hence, dismissed the petition.

[12] In U.S. v. Homestake Mining Company, 595 F.2d 421 (8th Cir. 1979), the court vacated the district court's order granting Homestake relief from the Consent Decree. The court ruled that Homestake was not entitled to a compliance extension under section 309(a)(5)(B) of the Clean Water Act, because its permit limitations were governed by state water quality standards rather than technology-based guidelines. The court, however, did not rule out a future good faith equitable defense by Homestake under Rule 60(b).

[13] In Homestake Mining Company v. EPA, 477 F. Supp. 1279 (D. S.D. 1979), the district court upheld EPA's approval of South Dakota's water quality standards under 33 U.S.C.

During the course of all this legal maneuvering, it became clear to EPA, Homestake, and South Dakota officials involved that little was being gained by any party or the public. From Homestake's perspective, the litigation was not successfully providing any basis for long-term corporate planning, and it certainly was not aiding its corporate image. Moreover, Homestake's potential liability in civil penalties was growing by the day. From EPA's and South Dakota's perspectives, the litigation was not producing any tangible environmental results, and it was merely delaying constructive efforts to address the technical problems in engineering a wastewater treatment system that would treat effectively the cyanide and heavy metals in Homestake's effluent.

Several meetings were held among EPA, Homestake, and South Dakota during which a clear change in attitudes became apparent on both sides of the negotiating table. The discussions began to center, not on the legal positions, but on the technical issues. The lawyers holstered their six-shooters as the engineering staffs explained that the chemistry of Homestake's effluent was posing unique treatment problems.

As an outgrowth of this new attitude, the respective technical staffs arranged to meet for candid technical discussions without the lawyers present. They agreed that a solution to the treatment problem would require a major research and development program by Homestake, and further recognized that the treatment process development would be most productive with the close involvement of EPA and South Dakota. All parties agreed that pending litigation should be settled, and the lawyers were charged with drafting what was to be characterized as an "engineer's" Consent Decree that would maximize engineering flexibility within the confines of an enforceable document. As part of the settlement Homestake would also pay a stipulated fine of three hundred and ninety thousand dollars, of which three hundred and fifty thousand dollars would go to South Dakota for a Whitewood Creek rehabilitation project.

IV. THE TECHNICAL PROBLEM

Because the Homestake facility at Lead is a combined mine/mill complex, Homestake uses the excess mine water (which must be pumped from the mine) and recycled process water from the tailings pond[10] in its milling process. The net volume of mine water, however, exceeds the mill's requirement for process water, thereby preventing total recycle and necessitating a

§ 1313(c)(2), finding that, under the FWPCA, states could adopt stringent technology-forcing standards without necessarily considering economic and social factors. In Homestake Mining Company v. Board of Environmental Protection, S.D., 289 N.W. 2d 561 (1980), the South Dakota Supreme Court reversed and remanded on procedural grounds a circuit court decision that had generally upheld South Dakota's standards. The circuit court action was later settled.

[10]The mill tailings consist of the ground ore remaining after the gold has been removed. The tailings are transported in slurry form and the water in the slurry contains heavy metals and process reagents, principally cyanide.

discharge. Homestake's discharge consists of a mixture of mine water and tailings pond decant water. While the mine water is of comparatively better quality than the decant water, it also contains heavy metals and cyanide. The mine water picks up cyanide from the sand fraction of the mill tailings that are used in the mine to backfill open areas. As cyanide drains from the filled areas, it mixes with other mine water.

When Homestake's NPDES permit was developed, the flow limit and effluent limitations were based on the more stringent of either the existing Best Practicable Technology (BPT) guidelines or the numeric limits calculated to comply with the State Water Quality Standards for a fishery. For the most part, the water quality standards were controlling. Table I shows a comparison of these values.

TABLE I

Parameter	BPT Limit (40 CFR 440.22)* mg/l	WQS Limit mg/l	Permit
Total Suspended Solids	30	10	10
Arsenic	N/A	0.38	0.38
Cadmium	0.1	0.00025	0.00025
Chromium	N/A	0.85	0.85
Copper	0.1	0.009	0.009
Lead	0.4	0.28	0.28
Mercury	0.002	0.001	0.001
Nickel	N/A	1.25	1.25
Silver	N/A	0.001	0.001
Zinc	1.0	0.020	0.020
Cyanide	0.02	†	0.02
pH	6 to 9	N/A	6 to 9

*40 Fed. Reg. 51722 (Nov. 6, 1975).

†"Quality Criteria for Water," United States Environmental Protection Agency (July 1976), indicated that an instream value of 0.005 mg/l total cyanide would be necessary to protect fresh water aquatic life. With the available dilution ratio, this would require an effluent limitation of approximately 0.017 mg/l.

All parties originally recognized that Homestake's effluent limitations were very stringent. Such stringent limits are often necessary on water quality limited streams. However, the relatively high quality of Homestake's untreated waste stream initially appeared to offer an advantage in designing a conventional treatment system using settling, ozonation (oxidation), and carbon adsorption.

When Homestake's ozonation system resulted in high cyanide levels in the effluent, it was discovered that the untreated wastewater actually included heavy metals, cyanide, metal-cyanide complexes, and thiocyanate (sulfur bound to a cyanogen group, SCN). It became clear that a system designed for heavy metals alone and cyanide alone was not going to effec-

treatment system to treat heavy metals and total cyanide in its effluent. The Decree contained no specific effluent limit goals because it was implicit that the system constructed would have to enhance the state-of-the-art even to approach permit limits. Under the Decree Homestake would provide monthly progress reports to EPA and the state, and technical representatives of both agencies would attend quarterly meetings with Homestake to discuss and evaluate the results of the company's research. This was to be a completely open development process.

Although the Decree contained a target date for construction of a treatment system, the critical path approach also necessitated provisions for intermediate decision points to allow for additional time and investigation of promising alternatives. Paragraph III, 4.(e) of the Decree provided:

> Compliance dates for construction of a treatment system may be extended if, by March 1, 1980, Homestake's research has identified a promising technology that is mutually determined to be worth pursuing, or if additional time is then mutually agreed to be necessary before process design can begin. In the event the process developed is mutually judged to be of sufficient complexity that the listed times are insufficient for adequate engineering, pilot plant testing, detailed process design, construction and operational startup, an additional mutually agreed upon extension may be granted.

For this Decree to work, the candid exchange of information among the parties would be essential. Reliance on such cooperation was a gamble but all parties agreed it was worth the effort. The Decree was approved and entered by the court on February 12, 1980.

VI. PROGRESS UNDER THE DECREE

Homestake's initial research effort involved numerous consultants, Homestake's corporate and local staff, Environment Canada, South Dakota, and EPA. The focus of its research included every known cyanide destruction technique and evaluated the potential application of those techniques to Homestake's effluent. The following technologies were evaluated in detail:

- Ozonation
- Air Sparging/Acidification/Volitization
- Ion Exchange
- Alkaline Chlorination
- Prussian Blue Precipitation
- Hydrogen Peroxide:
  - a. followed by lime precipitation
  - b. followed by ion exchange
  - c. followed by ferric ion addition
- Biodegradation

Simultaneously, analytic methodologies were developed that would accurately measure the cyanide in Homestake's effluent.

tively treat a waste stream that contained significant amounts of metal-cyanide complexes and thiocyanate. To further complicate the situation, Homestake also discovered that the EPA-approved analytic method for measurement of total cyanide was inaccurate at the levels contained in the permit because of the complex chemistry of the effluent. Homestake was thus faced with both a major treatment problem and an analytic problem.

V. THE LEGAL PROBLEM, DRAFTING AN "ENGINEER'S" CONSENT DECREE

The technical problems posed by the chemistry of Homestake's effluent also created some difficult regulatory problems. Since Homestake would be researching and attempting to develop a system that was beyond the current state-of-the-art, any workable agreement among the parties had to recognize the uncertainties inherent in the scientific process and provide for engineering flexibility. At the same time it was essential that the regulatory agencies be plugged into the process to assure themselves of the integrity of the research and development effort. The lawyers, therefore, agreed to draft the Consent Decree to reflect engineering objectives and a critical path approach.

From EPA's perspective, however, the legal problem in adhering to the engineering objective was that the uncertainty of engineering reality in this case ran square against EPA's policy requiring that Consent Decrees always specify the ultimate numerical standard or level of performance that a source must meet.[11] This EPA policy is based on a premise that Consent Decrees should not be used, or appear to be used, as a legal substitute for regulatory or statutory change. Nevertheless, EPA recognized after much internal debate that the environmental objective for purposes of this Consent Decree was to have Homestake design, build, and operate the best state-of-the-art treatment system possible, and that no one could realistically predict what level of effluent that system would ultimately produce. In other words, while no one could anticipate whether Homestake's system would ultimately meet the stringent numeric water quality limitations contained in its NPDES permit, from the standpoint of environmental results it was preferable to reach agreement on constructing the system and evaluating its performance capability. The complex legal issues of enforcing or modifying Homestake's permit could then be dealt with after the Consent Decree terminated, when an operational system would be on line and actual performance data available.

With the environmental results objective in mind, the lawyers defined the ultimate goal of the Decree simply as construction by Homestake of a

---

[11] The EPA policy requiring that Consent Decrees specify ultimate standards or levels of performance was reaffirmed in EPA's "Guidance for Drafting Judicial Consent Decrees" May 12, 1983.

Detailed process development focused on a chemical system based on hydrogen peroxide. The chemical system looked as though it would produce a reasonably good effluent, but it would be very costly to operate and would not remove the thiocyanate. Almost as an incidental part of its research, however, Homestake was looking at biological pretreatment as a possibility for reducing operating costs of the chemical system in the future. During this program, Homestake discovered that certain bacteria from the mine have an affinity for cyanide. Further investigations showed that these bacteria could actually be seeded on rotating biological discs similar to those employed in treatment of municipal wastewater, and a highly promising and efficient form of biological cyanide destruction could be achieved. This process would also remove thiocyanate and a substantial portion of the remaining heavy metals.

Since EPA and South Dakota technical staff had been active participants in the Homestake treatment process development, they were well aware of the significance of Homestake's preliminary tests using bacterial treatment.

In June 1981 Homestake presented a proposed engineering/construction schedule premised on the lead times necessary for development of a biological treatment system. The proposal also stated that the chemical system that had been developed would still be implemented if further development of the biological system should run into serious problems. The schedule projected a mid-1984 completion date. While the 1984 date would entail a substantial extension of the original September 1981 compliance date in the Consent Decree, the technical staffs of all parties unanimously agreed that the extension was warranted under paragraph III, 4. of the Decree. The Decree was, therefore, modified and approved by the court on January 24, 1983.

To date Homestake had authorized nearly $7 million for biological treatment plant construction and equipment purchases. The results of continued pilot testing look highly promising.

With the elimination of Homestake's tailings and the untreated municipal sewage from Lead/Deadwood, Whitewood Creek today runs clear and supports basic aquatic plants and insects. But the final chapter in the stream's recovery is yet to be written. If Homestake's biological treatment system is completed on schedule and proves effective, Whitewood Creek may, after one hundred years of sterility, once again support a fishery. Whether this goal is attained remains to be seen, but without the cessation of legal confrontation and the resulting cooperative effort by EPA, Homestake, and South Dakota, the current prospect for recovery of Whitewood Creek would not be nearly as likely. Given the progress that has been demonstrated to date, there is certainly room for optimism. There is a great deal at stake in the continued success of this cooperative approach to environmental regulation that may go beyond Whitewood Creek to serve as a model for resolution of complex environmental problems in the future.

CHAPTER 9

KEY CONTACTS AND EXPERTS ON REGULATIONS CONCERNING EFFLUENTS AND SOLID WASTE DISPOSAL

It is not always easy to determine the status of environmental protection regulations for a particular proposed mining operation as these pertain to effluents, mine and mill waste disposal, etc.

The following list of names and addresses is a long way from complete, nor has it set out to be complete. What is is is a list of those people who came to the attention of RANDOL INTERNATIONAL LTD. during the course of this investigation.

Starting with these contacts, it should be possible to auger into further contacts.

One source of information is, of course, the regulatory authority involved. However, it was the author's experience that sometimes just finding out what state department has jurisdiction over a particular water quality aspect is a time-consuming undertaking in the U.S.A.

In South Africa and Canada, it is a much more straightforward matter to find the appropriate government contact, and one is certainly dealing with fewer of them to achieve a given goal.

CHAPTER 10

COMPUTING WATER AND SALT BALANCES

Water balance modeling in mine-mill complexes would be easy were it not for problems relating to salt or contaminant buildup to levels that either present an effluent discharge problem (i.e., because they do not meet effluent discharge permit requirements) or because they cause interferences when the water is recycled to certain parts of the mineral processing sequence. Water quality effects are also important factors in corrosion and scaling phenomena.

Consequently, in solving problems in existing plants or in designing a new operation, it has become essential in many cases to carry out salt balance modelling to examine various process and water management alternatives. Modelling salt balances represents a much bigger challenge than does water balance modelling but, of course, the two go hand in hand.

One of the problems is that when complex solutions are mixed, i.e., solutions containing a range of cations, anions, and suspended solids, and a variety of residual organic reagents, oils and greases, and surfactants, as well as dissolved gases, it is not possible to predict reliability from theoretical or classical chemistry exactly what the resulting solution composition will be; that is, unless the solutions involved are all so dilute that all the species remain in solution. However, when solutions are cascaded and recycled repeatedly as is necessary in most mine-mill complexes, salt levels in solution build up until some become saturated or even supersaturated.

When dealing with a new process, it is usually recycled water rather than fresh water that comes in contact with the ore. Of concern is the chemistry of mill solutions after they have been in contact, not only with the ore particles, but also the gangue. Ions may precipitate from solution as well as be dissolved.

To accurately predict what recycle solution chemistry at various steps in a mine-mill complex will look like with respect to both major and trace element constituents requires a huge body of empirical data on actual cases. Unfortunately, no such data bank exists, and the cost of collecting one would be beyond the means of most companies, let alone their mineral processing departments.

The closest that industry has come to being able to model salt and water balances to predict the dynamic composition changes in water management systems is the Calgon Corp.'s calgard program for power plant water recycling. Based on many hundreds of thousands of solution analyses in actual power plants around the world, Calgon has built a program on this empirical data which can predict solution compositions, their scaling

and corrosion characteristics with respect to different materials, and the dosage of various water treatment chemicals required to avoid scale or corrosion. This phenomenonally useful program and data base was developed at a cost of $6-8 million over several years, but it is not designed for mine-mill water systems.

CH2M HILL
Post Office Box 2090
Milwaukee, WI 53201
(414) 272-2426
Michael Harris

A short description by CH2M Hill on water balance modelling approaches is inserted below.

From a more physical point of view, it has become necessary to model water balances where purely the volumes of water gained by precipitation, lost by evaporation, or with tailings in the impoundment. This is necessary to compute the amount of new water that will be needed for an operation in the dry season or in areas where there is a net evaporation, and to compute whether impoundments, runoff diversion measures, water treatment facilities, etc. are adequate for the volumes of water generated either during temporary wet seasons or from year to year as impounded water volume grows.

Many companies have the capability to compute water balance models of this sort. A schematic illustration of some of the parameters to be taken into account is provided below.

Recently, a major long-term water balance simulation was undertaken for the new McLaughlin project of the Homestake Mining Company in California. It was designed to compute the water balance and impoundment needs as well as the requirement for the

operation over a twenty-year period using various climatic assumptions--e.g., several years of drought, or several wet years with high precipitation. This useful program was developed by:

STEFFEN ROBERTSON AND KIRSTEN
7510 West Mississippi Avenue, #20
Lakewood, CO 80226
(303) 936-8254
Ian P. G. Hutchison

Dr. Ian Hutchison presented an interesting description of how this type of water balance modelling is undertaken for heap leaching operations as well as to be used as a tool in designing civil engineering aspects and tailings impoundments for conventional mine-mill complexes.

Randol International Ltd. has borrowed a water balance diagram from a tailings impoundment and drafted a table for computation of a water balance for this case as an example of how such a balance is computed for a tailings impoundment.

This table was carried around on several plant visits in the hope of collecting data to show a few examples, but it appears that this kind of data is not routinely monitored at most mine-mill sites. This type of data is used, it seems, primarily in the tailings design and permitting phases of operations.

FRITZ (1984) described some practical applications in mining hydrology and howed how a desktop PC can be used as a powerful tool for water balance computing for mining operations. He can be reached at:

WESTERN WATER CONSULTANTS, INC.
Sheridan, Wyoming
Doyl M. Fritz

FRITZ (1984) Some Practical Applications of Computers in Mining Hydrology. AIME Local Chapter Meeting, Rapid City, South Dakota.

Another world leader in groundwater hydrology and water balance modeling for tailings impoundments is Dames & Moore who, in 1984, were completing a water balance for Rossing Uranium Ltd.

2: Flow component (12) is the sum of (7), (8), (9), (10) & (11) in the example diagram.
3: Typical assumed dry density of Tailings of around 65 lb/cu ft. is between initial settled density 40-50 lb/cu ft and final settled density 75-90 lb/cu ft for Grey Eagle example.

Additional Notes and Comments:

WATER BALANCE MODELING

OVERVIEW

Water and wastewater management in mine-mill complexes has become more complicated over the past two decades with the enactment of environmental regulations and conflicting demands for available water resources. Water which might previously have been discarded after limited use (for example, once-through cooling water) is now recirculated or is used as feed to another water-consuming process in the plant. Water is now discarded as wastewater only after its quality has degraded beyond the point where further use is infeasible (or the volume is too great such as in high precipitation areas).

Water recycle and cascade water reuse is generally limited by the buildup of dissolved solids or an accumulation of some troublesome constituent. For this reason, it is useful to define water management objectives in terms of both water balance and salt balance components. Consequently, the "product" of a computerized water balance modeling exercise is a forecast of the water and salt distribution at discrete points throughout a mine-mill complex, including composition-based process performance predictions (e.g., precipitation or scale formation).

PURPOSES OF WATER BALANCE MODELS

There are several common reasons for performing a water balance modeling study. The usefulness of such modeling can extend to planned and existing facilities.

Modeling is commonly used to identify water and salt related process problems during design. These problems can include scale formation, precipitation upstream of or inside sensitive process equipment, leaching or other chemical changes. Similarly, wastewater quality and quantity estimates can be made for permitting of new facilities, and the effects of process changes on wastewater quality in existing plants can be assessed when selecting among various regulatory compliance options.

A flexible model is invaluable when assessing how much water quality parameters may change with various process, meteorological, or ore grade changes (sensitivity analysis). This is important when it is necessary to minimize raw water intake or eliminate wastewater discharge.

APPROACH

Water balance modeling consists of describing the water flow diagram and salt components (ion by ion) in a "link-node" format on a computer. The nodes represent the various unit operations which in some way modify the composition or quantity of the water (and salt), and links represent flow paths (pipes) between the unit operations.

The steps involved in setting up the computer program and running it are summarized in the following basic sequence.

- Define the objective(s)--evaluate reuse options, meet pollutant discharge limits, look for potential heat exchanger scaling, or other objectives.

- Identify constraints--regulations, water quality requirements for sensitive equipment, costs, existing problems, schedule, etc.

- Prepare a process diagram indicating major piping and the unit operations. This flow diagram is then introduced into the computer in link-node format.

- Prepare a water balance by identifying sources and sinks of water, assigning flowrates to the links, describing the water balance relationship around each node (unit operation), and finally, setting conditions for water balance closure around the mine-mill complex.

- Prepare a salt balance by selecting the important dissolved species, choosing "sampling" locations in the link-node diagram that permit salt balance closure, and using experimental data bases (<u>not</u> theoretical simulations). Enter into the computer program the effect that each unit operation has on each constituent in the water, set criteria for calling out special attention such as scale formation, and impose the requirement of electroneutrality (equivalence of positive and negative ions).

- Compute stream compositions by iterating the program until convergence is attained.

This necessarily abbreviated description suggests a fairly complicated sequence of steps leading up to the actual computation of a water and salt balance. However, many of these steps have been completed for previous modeling efforts and need not be repeated. This results in considerable ease in applying the model to new systems. Most importantly, the extensive compilation of available experimental information on how a wide variety of ionic species behaves provides the basis for producing more realistic simulations than would be possible with the more common theoretical models.

Computer modeling as described above has been used extensively for evaluating water management options in mine-mill projects, and the techniques are readily adaptable for use with a wide range of water management configurations. Further details can be provided by Mike Harris (414/272-2426) or Jim Mavis (206/453-5000).

Abstract. A generalized network flow computer model called MODSIM, has been successfully applied to integrated water supply and quality control analyses for a planned gold mining project in California. The program has proven to be particularly well suited for design and operational studies for the various facilities associated with the project. The results of the study have demonstrated the usefulness of integrated water balance evaluations in the designs for complex mining and civil engineering projects.

Introduction

The planned McLaughlin Gold Mine Project, located in Napa and Lake County, California (Figure 1) includes a system of interrelated water supply and water control facilities that must be designed and operated in an integrated fashion. During design studies for several of the facilities, including the tailings impoundment grinding and low grade ore stockpile areas, it was noted that the wide range of potential hydrologic conditions at the site had a significant effect upon the overall project water balance considerations. The water balance for such facilities had a direct influence upon water supply and quality control aspects of the project. The water balance for the individual facilities was particularly sensitive to the rate of water use from other project water sources. For these reasons, integrated water balance studies utilizing a generalized network flow computer model using the out-of-kilter algorithm, were initiated for the entire project.

Project and Site Description

The McLaughlin Project will be an open-pit mine, processing up to 3,000 tons per day of gold bearing ore. The mine will operate for 24 years producing an estimated 26 million tons of ore. The ore will be crushed at the mine site and slurried to processing facilities. Process tailings will be disposed of in an impoundment adjacent to the process facilities. A layout of the various project facilities is shown in Figure 2. A summary listing of the various project facilities considered in the integrated water balance studies is given in Table 1.

Figure 1. Project Location Map

Table 1. Summary of Project Facilities Considered in the Integrated Water Balance Studies

Facility	Design Storage Capacity (acre-ft)	Comments
1) Water Storage Dam	6,000	
2) Tailings Impoundment	22,000	Zero discharge system. 1,000-year, 24-hour flood event freeboard required
3) Mine Pit	--	Specified maximum allowable pit water buildup.
4) Water Quality Control	310	Zero discharge system. 100-year, 24-hour flood event freeboard required.
5) Grinding Facilities	--	Average water demand = 480 gpm for ore slurry production (minimum clean water required = 107 gpm)
6) Process Facilities	--	Average water demand = 1,050 gpm for tailings slurry and 207 gpm for evaporative losses (minimum clean water required = 200 gpm)

The climate in the vicinity of the project is dry summer subtropical. It is characterized by warm summers and mild winters. More than 90 percent of the annual precipitation occurs during the six month period between October and March. Most precipitation occurs as rainfall. Some snow may fall during the winter months, but snowpack is not formed.

The recorded precipitation ranges from a low of 9.1 inches to a high of 55 inches, with a mean annual precipitation of 33.5 inches. The mean annual evaporation in the area is approximately 48 inches. A total of 51 years of site specific hydrologic data has been developed for the various project design studies.

Description of MODSIM

MODSIM is a water management computer model originally developed by the Texas Water Development Board in 1972, and subsequently modified at Colorado State University (CSU).[1] It was selected for use with this project because of its generalized structure and capability of modeling water allocation in a system under policies and priorities as specified by the user. Although it was originally developed as a river basin model, it has proved adaptable to water systems at a much smaller scale.

In MODSIM, the water system is defined as a series of nodes and links. The nonstorage nodes represent points of inflow or diversion, and consumptive or flow-through demands. Storage nodes corresponding to reservoirs have user specified area-capacity tables, monthly target operating levels, and net evaporation, precipitation and seepage losses. Each water use is assigned a priority number, which translates into a nega-

Figure 2. Project Facilities Layout

tive cost. The nodes are connected by a series of one-way links, which may represent river reaches, canals, or pipes. Each link is given maximum and minimum capacities and and an associated transport cost. These costs may reflect actual costs, e.g. pumping; or they may be manipulated to favor certain flow paths.

Flows in the system are analyzed on a monthly basis. Inflows are added to the water currently stored in the system, and the water is routed to meet demands or reservoir storage goals, so as to minimize the overall systemwide cost. Spilling from the system is allowed if no other destination is possible, and is avoided by assigning to it, the high cost. MODSIM uses the out-of-kilter algorithm to calculate the most favorable routing, subject to flow and storage capacities. This algorithm iteratively determines the least-cost solution for any configuration of a circulating network.

The CSU version of MODSIM has been modified for use with the McLaughlin analysis. Some changes

[1] Shafer, John M., An Interactive River basin Model: Synthesis and Application, Technical Report No. 18, Colorado Water Resources Research Institute, Colorado State University, Ft. Collins, Colorado 1979

were required to fit the model on an IBM Series I, while others were made to tailor the output to the needs of this project. The present model is able to write over fifty years of results to disk storage. An auxiliary program, MODSUM, has been written to allow selective printing of results and statistatical summaries.

Description of Project Model

The objective is setting up a model was to develop a tool which would assist in sizing the water storage and control facilities and to develop operating procedures that would maximize use of available storage during dry years and minimize the potential for spillage during wet years. The system of links and nodes used for modeling the McLaughlin Gold Mine Project are shown in Figure 3. Twelve nodes have been created to represent six physical areas; the extra nodes are used to simulate special usage conditions. The nineteen links correspond to planned or potential connections.

1. Davis Creek Reservoir. The 6,000 acre-foot reservoir is supplied by the runoff from a 10.16 square mile natural basin. The reservoir is the only source for the clean water demands at the grinding and processing facilities. It also serves as a backup for other water needs at the mine, but pumping costs make it less desirable than more proximate, alternative sources. A synthetic node downstream from the reservoir allows overflow of the good quality water without the penalty normally attached to spilling from the remainder of the system.

2. The Mine Pit. The pit requires 136 gpm during the winter months and 272 gpm during the summer for dust suppression. When this water is not available from its own inflow or storage, it must come from Davis Creek Reservoir. Inflows consist of groundwater seepage and runoff from the pit area. The pit is modeled as two nodes, one which must be kept relatively dry for mining, and the other which may temporarily store up to 200 acre-feet. The capacity of the pit will vary with time, especially during the first ten years of operation. Excess water from the pit may be pumped to the grinding facility or to Pond M1. Other alternatives considered for the management of excess pit waters included pumping to the tailings impoundment, or water quality control Pond W1. Since discharge of this water is undesirable, a high penalty is attached to spilling.

3. The Tailings Impoundment. The tailings impoundment has a maximum capacity of 22,000 acre-feet. It receives the runoff from a catchment of 315 acres, but its major source of inflow is 1050 gpm of slurry from the processing facilities. Depending on the scenario, it may occasionally receive excess water from the mine pit. Consumption of water includes that which is retained in the tailings and surface evaporation. The pond

Figure 3. System of Nodes and Lines Established For the McLaughlin Project

has been divided into two nodes to represent the main pond and a synthetic pond which represents accelerated evaporation due to tailings management techniques. Water from the tailings is recycled to the processing facility to meet its water demands and as a water balance consideration for the tailings impoundment.

4. The Grinding Facility. This facility grinds the ore and pumps it in slurry form to the processing facility. It requires 480 gpm, of which 60 gpm is the minimum clean water requirement. A small supply of water is derived from the incoming ore, but most of the demand is met from outside sources. These sources, in order of preference are the mine pit, Pond M1, the tailings and Davis Creek reservoir.

5. The Processing Facility. This facility is represented as two nodes to model its demand for 207 gpm for consumption, and 1,050 gpm for slurry flow-through to the tailings pond. Of this, there is a minimum clean water (i.e. non-recycle) requirement of 200 gpm. It has a small inflow of runoff from a 20.5 acre basin, but receives most of its water from the ore slurry. The remainder of its water is supplied from the tailings impoundment or from Davis Creek Reservoir.

6. Pond M1 has a dual function as a water quality control structure and as a water supply for the grinding facility. Its major source of inflow is runoff from 178 acres. Since 80% of this area will be disturbed by mining, the water may be of poor quality and should be consumed either at the grinding facility or by evaporation. When the pond is below its operating capacity, it is also used to store excess water. The pond's function as a water supply for the grinding facility is important during the dry seasons. Its supply of runoff may be enhanced by collection of waters from a 54.9 acre natural drainage basin. This runoff is diverted from the site unless Pond M1 is below its optimum operating level. Since the two functions of supply and spill prevention are potentially in conflict, the model is particularly important for testing the operating rules for this pond.

Results of the Study

The model was run for a ten year period which included sequences of extreme wet and dry years. Operating procedures were established to minimize the potential for spillage during wet years and to maximize the use of water from all sources during dry years. The model runs were used to evaluate the effectiveness of these operating procedures and the designs of the various water storage and conveyance facilities. Iterative runs were carried out to refine both the operating procedures and the designs. Some highlights of the study results illustrating the versatility of the program are as follows.

Processing Facility Water Supply

Water for the processing facility will be derived from four sources: 1) Ore slurry water (from the grinding facilities) 2) tailings recycle water 3) clean water from the water supply reservoir, and 4) runoff from the process facilities area (requiring containment for water quality purposes). The integrated study results indicated that all water demands of this facility above the minimum clean water flow requirements (see Table 1) can be provided by runoff waters from the mine pit and water quality control pond M1 (utilized in ore slurry production) and recycled water from the tailings impoundment. A typical summary of these results are presented in Table 2.

Grinding Facility Water Supply

Water for the grinding facility will be derived from four sources: 1) Runoff and groundwater accumulation in the Mine Pit, 2) runoff contained in Pond M1, 3) clean water from the water supply reservoir, and 4) when necessary, recycled water from the tailings impoundment. The results indicate that all water demands of this facility above the minimum clean water flow requirements (see Table 1) can be provided by waters collected in the Mine Pit and Pond M1, and, during extreme dry years, with minimal recycle from mine pit water stored in the tailings impoundment.

Mine Pit

The results indicate the potential for significant buildup of water in the mine pit. The management of the pit waters will be critical for efficient mine operation. Use of the program has provided the basis for establishing pit water management schemes and operating rules. Storage of pit waters in the tailings impoundment have a significant design impact which was predicted and available for inclusion in the overall impoundment design.

Water Quality Control Pond M1

The results indicate that Pond M1 can be successfully operated as a water quality control structure. Operating rules developed as part of these studies are successful at maintaining acceptable water levels in the pond. The typical set of results for water levels are shown in Figure 4.

Tailings Impoundment

The results indicate that the tailings impoundment can be operated as part of the integrated water management system and that it would meet the required design criteria of zero discharge.

Water Supply Reservoir

The sizing of a water storage reservoir for projects of this type are typically based upon operational studies without consideration of potenial water contribution from other sources. The results of these studies indicated that water availability from the mine pit, the tailings impoundment and runoff water quality control ponds has a significant effect upon the required size of the reservoir.

Conclusions

The study results provide a basis for design of many of the facilities, pipelines and pumping systems associated with the McLaughlin Project. Spe-

NOTES

(1) FOR THE YEAR SHOWN, THESE VALUES REPRESENT THE PERCENTAGE OF THE AVERAGE ANNUAL PRECIPITATION (31 inches). FOR EXAMPLE; IN 1936, THE TOTAL PRECIPITATION WAS 34.4." 34.4/31 = 111%

cific conclusions regarding the designs have been omitted for purposes of brevity. General conclusions reached during these studies are as follows:

1) Integrated water balance studies conducted for the McLaughlin Project have indicated sensitivities which would have remained unknown if the facilities had been designed on an individual basis only.

2) Integrated studies should be employed whenever possible for the sizing of water supply reservoirs and tailings impoundments for mining projects. Such studies can be particularly beneficial when water balance considerations are critical.

3) Operation guidelines and water management alternatives for water quality control structures and mine planning can be easily evaluated with computer models such as MODSIM. The particular advantages of MODSIM over many other similar types of models is that it allows the system configuration and all operating procedures to be input as data. The program then determines the flow regime which best suits the system constraints, and cost and operational guidelines

4) The computer program MODSIM also shows promise as an operational and forecasting tool for the mine. On a regular basis, the model could be used to forecast water storage conditions in the various facilities for a range of projected hydrologic conditions. These results could then be used to further refine the day-to-day operating procedures and to plan the provision of any emergency measures that may be required.

CHAPTER 11

REDUCING WATER CONSUMPTION IN MINERAL PROCESSING
WATER EFFICIENT METALLURGICAL FLOWSHEETS AND EQUIPMENT

Chapter 3 reviewed water use in mineral processing operations. It was observed that water consumption varies from operation to operation depending largely on the amount of water available and the traditional approach to water use in the mill.

Reduction of water consumption is likely to be of interest mainly to those operations where water is not abundantly available or where it is very expensive.

Again, it is pointed out that the water consumed in a metallurgical or mineral recovery process is not the only water required for an operation. The total water requirement varies tremendously, too, depending on what infrastructure must be provided for a mine-mill complex. If a townsite and accommodation must be provided for staff and mine labor, then a significant additional amount of water will be needed, possibly even exceeding that used in the mill. Here too, the degree of labor intensiveness of the operation will also have an influence on the water demand for the townsite. In South African gold mines, the rule of thumb is 0.4-0.8 m^3/d per man employed. Clearly, one way to save water is through savings at the townsite. These aspects are not discussed here. Also, one of the most effective ways of reducing water consumption is through tight housekeeping and operator education.

This chapter identifies and briefly describes some of the more water efficient metallurgical flowsheets and equipment items encountered.

WATER EFFICIENT FLOWSHEETS

Rössing Uranium

Water efficient aspects of the Rossing Uranium flowsheet are listed below. Details are provided in the Appendix 1 trip report.

- Greater use of recycled tailings return solution. This was made possible by acid-proofing the CCD thickener rakes using a polyurethane coating to prevent corrosion of the rakes made of stainless steel 316L.

- Use of tailings return solution as glandwater for pumps which was made possible by modifying the bearings and pump shaft to overcome what would otherwise be a corrosion problem.

- Leaching ore at 75% solids in the pulp.

- Collection of seepage from the tailings dam for recycle. Seepage quality is significantly improved over decant from tailings due to reaction with calcerous strata through which the solution seeps, precipitating many undesirable contaminants.

- Living with a slightly reduced efficiency of recovery by ion exchange adsorption due to higher salt load in the process solution.

- Drawing down the tailings pond water level so that a smaller surface area of pond is presented for evaporation.

- Careful scale and corrosion control measures due to the greater use of recycled solution.

- Choice of eluant allowing eluant and yellowcake decant solution to be recycled.

Apart from the above measures, the actual metallurgical flowsheet employed at Rössing is standard for a low-grade uranium ore by sulfuric acid leach. RÖSSING URANIUM LTD. reduced their net water consumption from 30,000 m^3/d to 14,000 m^3/d in 1984 which worked out to 0.39 m^3/t ore treated. This is an exceptional achievement. In due course, their consumption will increase again once their tailings pond level has been reduced to the level they desire, but it will still be around 0.5 m^3/t which is exemplary considering their flowsheet.

An important contribution to Rössing's water savings is certainly due to the excellent training programs provided by the company for operators. These are ongoing programs, and every operator is aware of his contribution to the water conservation program. Water to each section of the plant is metered, and operators and their foremen are called to account when their water consumption increases.

The correct channel through which technical information on Rossing Uranium can be requested is:

UNC, Morton Ranch Project, Wyoming

The Nuclear Regulatory Commission, during the late 1970's, insisted that every new uranium mill should evaluate the alternative of dry tailings disposal. Burns & Roe, in conjunction with Pechiney, was the first in North America to demonstrate that the efficient use of belt filtration could first save water and (more importantly as far as the NRC was concerned) offer the possibility of being able to dispose of dry tailings. The idea was that dry tailings containing less moisture could be disposed of in trenches in a way that would allow the tailings to be stabilized on a continuous basis thereby, hopefully, reducing the impact on the environment. Every new mill proposed at the time in the U.S.A. examined this alternative as a requirement for their NRC permit application. Unfortunately, the uranium boom was dead before the NRC got around to issuing permits, and no mills using dry tailings were constructed in the U.S.A.

The Morton Ranch project in Wyoming of United Nuclear Corporation examined the possibility of belt filtration followed by dry tailings disposal via conveyor belts to the tailings area. It was concluded that this procedure would not be practical in Wyoming due to the risk of the tailings freezing on the belt in winter and the likelihood of windblown losses from the conveyor in summer. Adequate water was available for the operation using CCD for solid-liquid separation, and the Wyoming climate made it possible for the plant to achieve zero discharge with the use of evaporation ponds. This project was anticipated to draw only 5.0 gpm fresh water from ground or surface sources, all process water requirements (683 U.S. gpm, 3,750 m^3/d) being provided by evaporation pond recycle and water pumped from the open pit mines. Of course, seepage into the mine pit really would be a draw on groundwater from the area.

The Morton Ranch environmental impact statement showed a net minewater consumption of 2,140 m^3/d to treat 1,800 mt/d ore or 1.19 m^3/t ore treated with an additional 1,580 m^3/d (0.88 m^3/t ore) recycle water from the tailings pond (i.e., via the evaporation pond).

In this case, clearly there is no need to conserve water as the mine pits need to be dewatered anyway, and this water would otherwise have to be treated and discharged if it were not to be used in the mill.

The Morton Ranch project is an appropriate example of a uranium mill where dry tailings disposal was seriously considered and evaluated but where it proved neither practical nor cost effective within the Wyoming climate and water balance constraints for the project.

NRC (1978) pointed out that solvent extraction was selected for uranium recovery from solution because it uses less water than resin exchange processes.

Compagnie Miniere Dong-Trieu, France

This operation, which belongs to the Empain-Schneider Group, is located about 70 km from Limoges, France. It is a small operation which, when visited by Randol in 1980, treated 200 tpd with a grade of 0.5% U_3O_5. The plant, designed and engineered by Spechim, Paris, practiced dry tailings disposal in open pits. The tailings dewatering and washing was achieved using two (70 m^2 and 25 m^2) Philippe belt filters. This volume of solids applied to a 70 m^2 filter at 10 cm cake thickness means that the belt would be advanced at 1.4 m/minute which allowed time for five counter-current washes. The operation was described in greater detail by RANDOL (1979), and more information could be obtained from:

The purpose of using belt filtration was to achieve optimum washing and a concentrated preg solution as well as compact dry tailings for below ground disposal at the location which is amidst a productive farm community. It was not established what the CM Dong-Trieu net water consumption is or what their motivation was for the installation of belt filters. This operation does serve to demonstrate that belt filtration and dry tailings disposal can be applied, bearing in mind that this is a small tonnage, high grade operation, yet they installed a 70 m^3 filter for 200 tpd of solids treated.

Rudnik Urana Zirovsky VRH, Yugoslavia

A Yugoslavia uranium mill, Rudnik Urana Zirovsky, which was commissioned in 1980, employs two 50 m^2 belt filters in parallel and disposes of dry tailings. RANDOL INTERNATIONAL LTD. did not visit this operation, but it has been learned that their motivation for using belt filtration was to reduce capital costs to achieve superior wash efficiencies and a degree of simplicity while also disposing of dry tailings allowing a greater degree of solution recycle, reduced water consumption, and minimized pollution of a local river by liquid effluents. The operation treats about 600 tpd. Names of contacts at the operation include Dusn Pensa and Smargo Logar, and the operation is located 12 km from the town of Skofja Loca Slovenia. Pioneer Uravan, Colorado

Uranium circuits can be designed to be still more water efficient by incorporating the following innovations which were proposed for use at a uranium mill in Colorado at a site where water availability was a major problem:

1) The Use of Counter-Current Leaching
2) The Use of Belt Filtration as Opposed to CCD for Solid Liquid Separation
3) The Use of Solvent Extraction Rather than CIX
4) Disposal of Dry Tailings

The use of counter-current leaching makes it possible to achieve a more concentrated pregnant solution. Two stages of counter-current leaching were proposed and tested for the Pioneer Uravan project. Testwork was performed at the Colorado School of Mines Research Institute. The project was ultimately shelved because the economics of uranium recovery changed, and the company was unsuccessful in finding adequate water for the project.

Counter-current leach results in a lower water consumption inventory need with a corresponding lower evaporation loss in the circuit. The greatest benefit is the higher solution tenor which allows solvent extraction to be employed rather than ion exchange. The greater selectivity of SX compared with CIX allows more extensive recycling of solution recovered from the tailings.

Belt filtration, if skillfully applied, allows counter-current washing of the leached pulp employing only 1.0 m^3/t ore washwater as opposed to 3 m^3/t required in a CCD circuit with an equivalent wash efficiency,

Solvent extraction is much more selective than resin ion exchange and does a better job of uranium recovery in the presence of competing ions which, due to the recycling of

solution to the degree planned for this project, would be a necessary process selection. The higher the tenor of the pregnant solution, the more efficient the solvent extraction step and the more cost effective as well.

Belt filtration is ideal for washing and dewatering the coarsely ground sandstone ore pulp because of its top-loading feature. In the CSMRI pilot plant, moisture content could not be reduced below around 30% which was higher than expected. Possibly on production scale units, the edge effects would be less of a factor, and mosture content of the tailings could be reduced closer to the 20% target.

The belt filters were planned to provide dry tailings for disposal with a minimum water content which would provide a major water savings.

In the pilot plant operations, TDS built up rapidly in the process solutions until eventually they reached a density of 1.2. In the filtration step, alum crystallized out in the filtrate receiver and the vacuum box, which presented a problem. Salt balance considerations are critical if water is to be recycled to this extent. Needless to say, special materials or coating would be needed to prevent equipment from being corroded by solutions with such high TDS levels.

In pilot plant belt filter tests at the Colorado School of Mines Research Institute, Golden, Colorado, it was found that in the counter current leaching step, that alum would crystalize in the vacuum box of the filter which ultimately interferred with the filter operation. Also, for an effective counter-current leach, it was found that a repulping step was needed between leaches. In the final design, the use of a thickener instead of a belt filter was found to be more cost effective.

Robert J. Polak was the project manager for Pioneer Uravan, and Daniel Blakeman supervised the CSMRI testwork during the final stages of the program. He and a senior metallurgist involved in the project can be reached as follows:

Belt Filtration in French Uranium Mills

In France, belt filtration was pioneered and successfully applied for uranium recovery circuits.

According to COGEMA, belt filtration of French uranium leach pulps provides successful washing when 2.0 to 2.2 m^3 solution is recovered per ton of solids as compared with 3.5 m^3/t ore for CCD pregnant solution.

Recycle water is used to supplement fresh water used to wash the filter cake.

A paper by BODU, et al. (1982) provided a comparison of CCD versus belt filtration for uranium ore processing.

Depending on the dissolved salt concentrations in solvent extraction raffinate, part of the raffinate can be recycled in the plant. However, appropriate settler capacity must be provided to remove solvent droplets. Somair in Niger uses a safety settler with a residence time of over one hour. Solvent droplets could damage rubber components (linings, belts, etc.) which are made of natural rubber. This danger is greater the higher the aromatic content of diluents used.

One comment made is that the best way to reduce water consumption in a plant is probably to fit a large number of recording flowmeters at appropriate places in the circuit.

In France, a COGEMA plant of LODEVE operated by SIMO and the SIMO plant of Bessines (after 1986) will dispose of dry tailings.

In Niger, the SOMAIR plant in Arlit uses belt filters and also disposes of dry tailings.

Belt Filtration: Rand Mines Ltd., Harmony

At the Merriesprut uranium plant in the Orange Free State, Rand Mines Ltd. installed belt filters with a view to conserving water. Their original plan was to apply multiple counter-current washes on the same filters. This proved impractical and, in the end, two co-current washes were applied. It is not known how much wash solution was applied, but it is expected that around 2.5 m^3 of pregnant filtrate is recovered per ton ore treated. According to C. E. Fivaz, former consulting metallurgist of Rand Mines Ltd., the soluble losses of uranium in the belt filter tailings amounts to about 4% which is very much more than was expected.

THE STRONG ACID AGGLOMERATION PROCESS

Ranchers, Naturita, Colorado

The Rangers Exploration Co. was the the first in the U.S.A. to use concentrated sulfuric acid agglomeration of uranium ore (actually roasted tailings) followed by curing and heap leaching in an impermeable pad. This was carried out at Naturita, Colorado. A process based on similar principles has been employed by COGEMA/PECHINEY at Arlit in Niger, Africa, and the British Atomic Energy Agency has patented a similar process.

The Ranchers operation treated 1,500 st per day (1,350 mt/d) and required only about 40 gpm net water or 229 m^3/d which works out to 0.17 m^3/t. Water was pumped from the adjacent river in summer and hauled to the site in winter. The acid cure released adequate heat to avoid freezing--also, the high concentration of acid lowered the solution freezing temperature.

The sandy, minus 48 mesh tailings contained 6-7% H_2O to start. During the saturated leaching step, they contained around 18% H_2O and then drained to 11-12%. Consequently, only about 0.05 m^3 new water was lost to entrainment per ton of tailings.

Because water recycle was so tightly controlled, dissolved salts built up in concentration, and the salt load was not balanced by entrainment in tailings. NaCl was used to strip the loaded organic phase in the SX plant. This resulted in chloride buildup which had to be controlled below 3 g/l in the recycled water. This necessitated about 30 gpm (165 m^3/d = 0.12 m^3/ton feed) bleed.

The Naturita operation worked with a very small water inventory and is possibly the most water-efficient metallurgical process identified to date. The concentrated acid cure served to "open up" the ore for good extractions despite the coarse grind. Concentrated acid mixed into the ore comes into contact with interstitial moisture in the ore grains and through the exothermic reaction of H_2SO_4-H_2O mixing, resulted in a good leach recovery in advance of the subsequent washing step.

Although the original Ranchers team has disbanded, the engineer who installed and operated the Naturita project can be reached:

GOLD AND SILVER HEAP LEACHING VS. AGITATION LEACH

At first glance, one might expect heap leaching, which employs spray irrigation and multiple pass solution applications for many days, weeks, and even months, to be inefficient with respect to water consumption compared with agitation leaching which takes hours.

It, in fact, turns out that heap leaching is very water efficient. Data gathered as part of this investigation and shown in Chapter 3 indicates that heap leaching in the western U.S.A. typically consumes only 0.2-0.3 m^3 new water per ton ore and, if need be, this can be reduced to 0.2 m^3/t ore average for the year. This compares with 0.7-1.5 m^3 water/ton ore used in conventional circuits. In both cases, precipitation adds water to the system, and evaporation results in solution losses. It is important to note that the 0.2 m^3/t rule of thumb is an average water requirement over the whole year. In colder months and during the spring melt, water needs will be very much less than this. In the hotter summer months, the water consumed per ton ore will be very much higher than the average.

Experiments in Arizona showed that when wobbler sprinklers are used for heap leaching, evaporation losses work out to 10-15% of the solution irrigated during summer daytime periods. By changing the droplet size of the spray, the rate of evaporation can be

modified as a means of adjusting the water balance as needed. There are innovative desert drip irrigation techniques which hold promise when water consumption has to be minimized.

There are four possible reasons that heap leaching requires less water than agitation leaching:

1) Ore is crushed and not ground. Consequently, tailings are disposed of with a much lower moisture content, say 10%, compared with 50% or so for milled tailings. This factor alone would account for a water savings of 0.40 m^3/ton ore.

2) Tailings ponds and recycle solution reservoirs in conventional leach operations are often not designed to be impervious, and considerable losses of water occur from some due to seepage. In heap leaching, solution ponds are plastic-lined, and water has already been recovered from the heap material by the time it is disposed of as tailings.

3) Heap leaching presents smaller surfaces of water for evaporation, i.e., it uses no tailings ponds.

4) In most cases, heap leaching does not need to bleed barrens. It appears that the heap material in many cases prevents buildup of metals such as Zn, Cu, etc. in solution. This observation requires confirmation, however.

The addition of concentrated cyanide solution during an ore agglomeration pretreatment followed by curing also saves water. The water recycling potential is enhanced by the addition of scale inhibitors.

MERRILL-CROWE VS. CIP FOR GOLD RECOVERY

The Merrill-Crowe (zinc precipitation) circuit arrangement which uses solid-liquid separation after leaching offers an opportunity, if need be, to recover solutions from tailings before they are discarded. This would be the case if a dry tailings disposal technique were to be used. So far, no gold or silver operation has been identified which uses this technique, although uranium operations in France and Yugoslavia do use dry tailings disposal. The Mahad adh Dhahab operation in Saudi Arabia plans to employ CIP followed by filtration for solution recovery to conserve water in this extremely arid part of the Arabian desert. It will be very interesting to learn what the net water consumption of this operation proves to be. In their case, the ore contains cyanide-soluble copper which will require a barren bleed unless some form of cyanide recovery/copper removal process in employed. Information on Mahad adh Dhahab was provided by LEWIS (1984), and further inquiries may be directed to:

CONSOLIDATED GOLD FIELDS LTD.
49 Moorgate
London
England EC2R6BQ
(01) 606-1020
Peter J. Lewis
Group Metallurgist

Normally, there is a tradeoff between CIP and Merrill-Crowe. CIP achieves a slightly better gold recovery, especially when the ore contains small quantities of cyanide-soluble base metals, but cyanide losses through the inability to recycle barren solutions are higher. Merrill-Crowe, because of the solid-liquid separation step, allows greater flexibility in water management. For example, reusable barrens can be returned to the plant, while water that is not so suitable for metallurgical use can be used for filtercake repulping and transport to the tailings pond, or dry tailings can be disposed of by conveyor belt. The Mahad adh Dhahab project will be combining both.

FOSTER WHEELER DRY CYANIDATION

The Foster Wheeler "dry" cyanidation process involves agglomerating a very coarsely-ground gold ore with concentrated alkaline cyanide solution and allowing the agglomerate to cure in vats in contact with an oxygen enriched atmosphere.

After essentially leaching gold values in the ore during the curing stage, values are next washed from the ore for recovery.

It is known that Noranda Research in Montreal evaluated the "dry" cyanidation process, but they have not used it at either of the gold plants that they installed since then. The engineer at Foster Wheeler who was involved in the development of the process, Dr. R. Balakrishnan, has left that company. Information about this process, which is not without promising features, particularly from a water conservation standpoint, could be requested from:

REFRACTORY GOLD ORE TREATMENT

The Homestake Mining Company at their McLaughlin project will use pressure oxidation to make their refractory gold ore amenable to cyanidation. This operation, which is now in a startup phase, is summarized in Appendix I. Sulfides and sulfosalts that encapsulate gold are oxidized and washed from the ore together with heavy and base metals. By keeping the wash solutions segregated from the cyanide leach circuit, the formation of metal cyanide complexes can be avoided which otherwise would result in metallurgical interferences and the need for more difficult cyanide complex treatment or disposal of a bleed.

By washing the oxidized ore and keeping the wash solutions separate, the base metals in solution can be removed by simple neutralization with lime and settling, allowing it to be reused in washing more oxidized ore.

A similar step can be used as effectively to remove soluble base metals from calcined concentrates prior to cyanidation with the same advantage of reducing the volume of barren bleed.

WITWATERSRAND GOLD-URANIUM CONCEPT

Witwatersrand ore is treated by alkaline cyanidation for gold recovery followed by sulfuric acid leaching for uranium recovery, or vice versa. This two-step process involves the addition of lime to get the high pH needed for cyanidation followed by acidification for uranium leaching and a final neutralization of uranium leach tailings in the "forward-leach" process and just as wide a swing in pH for the "reverse leach" process. In each step, large quantities of water are involved.

If both gold and uranium could be leached in either an acid or an alkaline pH and extracted together, a significant water savings would potentially be possible as well as a potential reagent savings. Cyanidation does not work at a low pH, and Witwatersrand gold ores do not leach well in carbonate or alkaline solutions.

One possible way is to leach gold in an acidified thiourea solution which would also leach uranium. It is believed that an improved thiourea leaching technology has been developed by SKW in Germany which involves the stabilization of thiourea using SO_2 or sodium sulfite addition. This is merely a concept at this stage demonstrating how a systems approach can be used to potentially improve water management, i.e., reduce water consumption in metallurgical processing.

COPPER-LEAD-ZINC FLOTATION

Conventional conditioning of pulps for the separation and recovery of copper, lead, and zinc concentrates from complex sulfide ores involves aeration and conditioning with SO_2. Various activators, frothers, collectors, and depressants are used. The presence of some of these and also of oxidation products due to partial oxidation of reactive sulfides in the ore or metals, e.g., Cu that may leach from oxidized fragments in the ore, can put constraints on the amount of water that can be recycled without interferring with the process. Similarly, the discharge of effluents may cause a problem in the receiving waters due to oxidation of thiosulfate which results in a drop in pH.

One plant that is wellknown for thiosalt generation is Brunswick Mining near Bathurst, New Brunswick. There was a limit to the amount of water that can be recycled due to metallurgical interference in some circuits, e.g., the Pb-Cu separation step; thiosalts in mill tailing solutions cause pH problems in the receiving waters. Numerous ways have been investigated to treat effluents to remove metals and thiosalts prior to discharge without finding an economical way. It is believed that BM&S, in conjunction with Lakefield Research, has developed a processing sequence that reduces the use of SO_2 as a conditioning reagent and which promises to allow 100% recycle of mill tailings decant solution reducing the amount of thiosalts discharged in effluents. The processing sequence is said to be simpler than the previous arrangement.

The implementation of the new process arrangement has just begun, and it is premature to seek out details. At some future date, these may become available from:

BRUNSWICK MINING AND SMELTING
CORP. LTD.

A. M. Wyslowzil
Manager

If successful, the BM&S mill hopes to reduce fresh water intake to an extent that effluent discharge from mill tailings can be greatly reduced.

BELT PRESS WATER RECOVERY FROM TAILINGS

Residual water content in some tailings never drops below say 60-65% H_2O because of the nature of the solids material. This not only means that 2 m^3 (tons) of water are tied up in the tailings pond for each ton of ore treated, but also that an expensive tailings impoundment will be needed because of the extra volume of water to be contained.

One alternative way in which, in some cases, water can be recovered and a more stable form of tailings produced that is suitable for "dry" tailings disposal is by squeezing the tailings. Innovative belt press devices have been installed for this purpose. The major market for belt presses is in dewatering sewage sludges, but they are also used for dewatering metal precipitates and in at least once case (WIDCO, Washington), for dewatering a clay-rich fine coal plant refuse.

LAROS, et al. (1985) will describe the use of the EIMCO belt press for cyanide and water recovery from a silver mill tailings material.

MOTIVATION

Motivation for the removal of suspended solids is generally one of the following:

- To meet effluent permit limits for suspended solids.
- To meet effluent premit limits for total metal values.
- The treatment of pregnant liquors prior to metal value recovery by solvent extraction, zinc precipitation, or crystallization.
- To avoid abrasion of water-powered hydraulic tools.
- To avoid abrasion wear on pumps used to dewater mines.
- Recovery of reusable values.

TECHNOLOGY GOALS

The technology goals and process selection criteria for suspended solids removal are:

- The removal of S/S from water to as low a level as possible.
- To produce a sludge with a high solids denisty.
- To yield a "non-hazardous" sludge which can be disposed of in a routine manner.

TECHNOLOGIES

Several technologies, some innovative, others costly but good, and others very simple have been identified for the removal of suspended solids. As solution recycling is required to an ever-increasing extent in mineral processing with resultant TDS buildup, such solutions can become highly scaling which present a downstream problem when polishing is required for the removal of suspended solids.

COAGULATION AND FLOCCULATION

Coagulation and flocculation are required to separate suspended solids from water whenever their natural settling rates are to slow to provide clarification. Water clarification, lime softening, sludge thickening, and dewatering and removal of trace quantities of suspended metal precipitates all depend on the correct application of the theories of coagulation and flocculation for their success.

NALCO (1979) includes the following table showing the settling rate of silica at different particle sizes which illustrates the effect of size.

Sedimentation of Small Particles of Silica of 2.65 Sp. Gr.

Typical	mm	Micron	Surface area (total)	Settling time, 1 m fall
Gravel	10.	10,000	3.14 cm^2	1 sec
Coarse sand	1.	1,000	31.4 cm^2	10 sec
Fine sand	0.1	100	314 cm^2	125 sec
Silt	0.01	10	0.314 m^2	108 min
Bacteria	0.001	1	3.14 m^2	180 hr
Colloidal matter	0.0001	0.1	31.4 m^2	755 days

NOTE: Particles larger than 100 microns are visible to the naked eye and are considered to be settleable solids. In the range of 10–100 microns, they are considered to be turbidity. Below 10 microns they are considered colloidal. Particles larger than 0.1 micron are visible by light microscope; below 0.1 micron, the electron microscope is used for detection.

It is fair to point out that the municipal water treatment industry is far ahead of the mining and mineral processing industry in their understanding and application of coagulation and flocculation technology. In the mining industry, the operator's concept of coagulation and flocculation does not go much beyond the hassles of making up and ageing flocculant solutions and dosing it somewhere--usually by injection into a pipeline or channel carrying solution ahead of a clarifier, thickener, or filter.

The water treatment industry employs separate equipment units for coagulation using high-energy flash mixers followed by low-energy mixing to allow the growth of the floccules formed in the first step to take place which is called flocculation.

A good understanding of the basic principles of coagulation and flocculation is provided by NALCO (1979) and in NALCO Bulletin 40, "Water Clarification: Questions and Answers," available from:

NALCO CHEMICAL COMPANY
2901 Butterfield Road
Oak Brook, IL 60521
(312) 887-7500
Robert E. Finch
Corporate Sales

The terms coagulation and flocculation are often used interchangeably; however, when seen as two different mechanisms, they can provide a better understanding of clarification and dewatering.

WHAT IS COAGULATION, AND WHAT IS FLOCCULATION?

COAGULATION

Coagulation is a chemical or physical process wherein the negative charge on colloidal turbidity particles is neutralized by a positively charged (cationic) chemical permitting them to collide and eventually to settle. This phenomenon is known as colloid destabilization or coagulation.

Coagulation is achieved in three steps:

1. Initial rapid mixing of coagulation chemicals with the water or solution to be treated.

2. Neutralization of particle surface charges.

3. Collisions between electrically neutralized particles caused by "rapid mix" energy input allowing the neutralized particles to coagulate into "floccules."

A coagulant is a chemical which, in solution, furnishes ionic charges opposite to those of colloidal turbidity particles in the water. Generally, coagulants are positively charged (cationic) and react with negatively charged clay particles which are a common cause of turbidity. Colloidal metal precipitates are usually hydrated or surrounded by OH^- ions and, therefore, also present a negatively charged surface. The cationic coagulants may be inorganic, e.g., alum, iron, or inorganic as well as organic polymers with cationic groups. The primary function of a coagulant is to neutralize charge.

(a) Coagulation: The addition of a coagulant neutralizes charges, collapsing the "cloud" surrounding the colloids so they can agglomerate. *(b) Flocculation:* The bridging of the flocculant chemical between agglomerated colloidal particles forms large settleable flocs.

Colloids are catagorized as hydrophobic or hydrophilic. Hydrophobic colloids do not react with water; most natural clays are hydrophobic. Hydrophilic colloids react with water and organic colloids which cause color are usually of this type. Hydrophilic colloids react chemically with coagulants and, therefore, require larger doses than are required for hydrophobic colloid coagulation.

Zeta Potential

The zeta potential is a measurement of the force which prevents colloidal particles from approaching close to each other or colliding, and this is determined by the charge of the ion layer surrounding the colloid.

For colloids in natural water sources in a pH range 5-8, the zeta potential is generally -14 to -30 millivolts; the more negative the number, the stronger the particle charge. As the zeta potential diminishes, the particles can approach one another closely, increasing the likelihood of colliding. Coagulation usually occurs at a zeta potential that is still slightly negative, so the coagulant addition need not completely neutralize the colloid charge. If the particles are all given a positive charge, they will redisperse.

Coagulants may be required at high pH as in lime softening or lime precipitation. Calcium carbonate carries a negative charge, and cationic coagulants may be needed to enhance their settling rates.

Magnesium hydroxide, on the other hand, has a positive charge until the pH exceeds 11, so in lime or lime-soda softening processes where $CaCO_3$ and $Mg(OH)_2$ precipitate, the oppositely charged particles co-precipitate.

Zeta potential is determined directly from data obtained in observing particle motion under a microscope. Zeta potential measurements have been used successfully to control plant coagulant dosages. However, for selecting the best coagulant, zeta potential readings alone are not reliable. The NALCO Water Treatment Handbook points out that for coagulant selection, the jar test remains the best.

Zeta potential is measured using a zeta meter available from:

KOMLINE-SANDERSON ENGINEERING CORP.

Telex: 136-328
Eric Jannelli
Sales Engineer

One of the most challenging colloidal suspension problems in mineral processing is encountered in diamond recovery operations in which oxidized kimberlite ore is crushed and washed. Suspended colloids up to 10-12μ or more are encountered in thickener overflow water as described in Appendix I in the trip report on the Premier Diamond Mine. More germain to sponsors of this study, however, are the effects of colloidal adsorption from pulp solutions onto activated carbon, which requires more research, and the use of engineered coagulation for removal of metal contaminant precipitate colloid from treated effluent solutions.

COAGULATION AND FLOCCULATION CHEMICALS

Historically, metal coagulants (alum and iron salts) have been most widely used in water clarification. These products function both as coagulants and flocculants. When added to water, they form positively charged species in a typical pH range for clarification of 6-7. Hydrolysis, however, yields an insoluble gelatinous aluminum or ferric hydroxide. Even if there are no suspended solids in the feedwater, the metal coagulants form flocs which enmesh destabilized colloids. However, the voluminous sludges produced by the addition of metal coagulants create disposal problems because they are difficult to dewater. This is the reason alum and iron salts are not often used to improve the efficiency of centrifuges, filter presses, and other dewatering devices.

Metal coagulants are particularly pH sensitive. If pH is not in the proper range, clarification is poor, and the iron or aluminum may be solubilized. The lower the coagulant dose, the more sensitive the floc is to pH changes as shown in the following diagram borrowed from NALCO (1979).

The effect of coagulant dosage on pH range limitations. The optimum pH remains almost constant, but the pH range becomes less restrictive as coagulant dosage increases.

In the 1940's, activated silica was introduced, and it improved the performance of alum and iron salts as coagulants and flocculants in water clarification. During the 1950's, the development of a range of organic flocculants called polyelectrolytes revolutionized water treatment technology. Polyelectrolytes are large water-soluble organic molecules. They usually incorporate ion exchange sites which give the molecular chains an ionic charge. Those having a positive charge, e.g., polyakrylamides, are cationic, and those with a negative charge are anionic. These polyelectrolyte molecules react with colloidal material in water by neutralizing charges or by bridging (tying together) individual particles to form a visible, insoluble precipitate or floc.

Cationic polyelectrolytes are designed to work at lower pH and anionics at higher pH. Nonionic and quaternary flocculants are only slightly influenced by pH. This general rule should not be interpreted to mean that anionic polymers do not work at low pH--it simply means that they are no longer ionic. They produce good results in flocculating solids at low pH simply because of their nonionic bonds. The same applies to cationics; even though they are not charged at a high pH, they may well be equally as effective because of their polar groups.

Organic polymers used in water treatment are of two major types, coagulants and flocculants. Coagulants are positively charged molecules of low molecular weight. Flocculant polymers have much higher molecular weights providing long bridges between small flocs to inhance particle growth. Flocculants are either cationic, anionic, or nonionic. Polymer flocculants, unlike coagulants, are not selected for neutralization.

Unlike inorganic salts, polymers do not produce voluminous gelatinous flocs. In applications where additional solids improve results, inorganic coagulants or clay may be required to supplement the use of polymers. Polymers do not affect pH, nor is their performance as sensitive to pH as initial coagulants.

ACTIVATED SILICA

Some inorganic compounds can be polymerized in water to form inorganic polymer flocculants. Activated silica is one example. When sodium siliute is diluted to 1.5-2% and then partially neutralized by the addition of Cl_2 or Na_2CO_3, the silica becomes colloidal and then begins to slowly polymerize. After aging for 15-30 minutes, the solution is diluted to 0.5-1.0% SiO_2 arresting further polymerization and producing activated silica. Although this preparation procedure is complicated, this is a very effective flocculant for applications such as alum treatment for color removal and improving the softening of organic containing waters.

COAGULANT AIDS

A coagulant aid is an additive which aids the coagulation process. It is finely divided colloid which may be surface modified which, when added to raw water, provides increased and more effective particle collisions during the initial neutralization step. Although these inorganic colloids (e.g., activated bentonite clay) may be compared with inorganic metal salt addition, they provide a different function, and they do not have the same disadvantages, such as the formation of hydrous polymerized floc structures which can give rise to dewatering difficulties in later sludge handling. These coagulant aids provide an effective means of building a sludge bed (where turbidity of the feed is low) and providing the additional turbidity needed to enhance the clarification process.

Several most innovative applications of this sort tailored specifically to the mineral processing and effluent treatment needs of mines and mills are demonstrated for an activated bentonite product by:

FLOCCULATION

Flocculation is the entrapment of neutralized particles into a larger solids network or floc. Although coagulation is a chemical reaction, the flocculation process in which floccules are adsorbed together to form larger flocs is mainly a mechanical process. In addition, molecular bridging may be enhanced by the use of flocculants. Flocculation results in a considerable increase in the size and density of coagulated particles resulting in a faster rate of settling of the flocs.

Flocculants are often "ionic," but their function is not to neutralize charged particles. The charge of the flocculant is primarily an indication of how it will uncoil in a given situation. The primary function of a flocculant is to provide a bridge between previously neutralized particles. These chemical sform larger floc particles that are dense enough to settle and which, in the process, also adsorb other coagulated particles, thereby enhancing the rate and efficiency of clarification processes.

FLOCCULATION IN PLACER MINING

Placer gold mining operations more often than not are located alongside or in a streambed or creek. Water requirements are nearly always drawn from the creek. Placer mining uses a large volume of water per ton of ore (1 yd^3 = about 2 t) for washing. Often, clay minerals are "scrubbed" from the ore in a trommel. Water containing suspended solids cannot legally be returned to the stream within permit rrequirements in North America and several other countries. This means that water is settled in a series of ponds before being returned to the process and/or decanted and discharged. The area of settling pond required can be extensive. Operating a flocculant makeup and dosing system to enhance settling rates and to reduce the size of the pond needed is possible but expensive to build and maintain. It also needs a power supply and a source of clean, fresh water with which to make up the polymer solution.

Hercules, Inc. has developed a new way of dosing flocculants using gel logs which are placed in the water stream and which dose according to the flow rate that comes into contact with the log. The application of gel flocculant to remote impoundment ponds has been described by MOORE (1982) in a technical report brochure titled "Treatment of Remote Impoundment Ponds with Gel Flocculants." This is probably not the ideal way to dose a flocculant to a system, but it is very simple and convenient and certainly would beat no flocculant at all. Information can be requested from:

COAGULANTS AND FLOCCULANTS IN MINERAL PROCESSING

Most texts on coagulation and flocculation deal with municipal water and wastewater treatment. Flocculation has been intensively used since the 1960's for enhanced settling of solids in CCD circuits and for improved filtration performance in metallurgical circuits.

Flocculants have also found application in solution clarificaton and polishing although examples have also been encountered where better overall extraction results are achieved by not adding coagulants or flocculants. One example of this was in the cone clarifier installed at Vaal Reefs South ahead of Stellar filter clarification before zinc precipitation as described by KUN, et al. (1979). Installation of the "Hopper Clarifier" using 5 mg/l $FeCl_3$ and an organic polymer alone resulted in an increase of the Stellar filter cycle from 4 to 40 hours. When $FeCl_3$ addition was discontinued, the cycle of the Stellar filter clarifier was increased to 170-200 hours. In this case, the shape of the suspended solids particle is such that it forms an accumulating "precoat" layer on the Stellar filter surface which enhanced the cycle time when particles of a particular species were not removed.

Chapter 4 refers to underground sludge removal from minewater in which the organic flocculant PERCOL is used to advantage in the AARL-CSIR cylindro-conical clarifier. Appendix I includes a trip report on the Mount Emmons water treatment plant installed by AMAX, Inc., which employs the DRAVO Lectrocoagulation process which works well for solutions with a low solids load. In the treatment of minewater and mill tailings decant effluents for discharge, often it is necessary to use flocculants and coagulants to enhance precipitate settling characteristics. The use of polyelectrolytes in settling of sewage sludges in municipal waste water treatment plants is also standard practice, and it is suspected by some that residual amounts of polyakrylamides may be one cause of interference in flotation processes when

treated sewage water is used in flotation circuits, but this has by no means been firmly established.

Coagulant and flocculant technology is largely based on empirical experience, and water treatment suppliers are usually the best source of information, e.g.:

ROSEN, et al. (1980) described an analytical method for rating flocculant performance. This is a simple technique for characterization of the performance of flocculants in various mining applications. The method utilizes three key parameters obtained from raw settling data and combines them into a single mathematical parameter called the desirability coefficient. The first two parameters are the times required for the slurry supernatant interface to fall to two selected fractions of the starting height, and the third is the clarity of the supernatant liquid. The relative values of the three parameters may be assigned different weights in order to make them correspond with laboratory and field performance requirements of a particular industry. Provision is also made of an internal comparison of test flocculant data with that of a control. This method was developed and described by development scientists of the UNION CARBIDE CORP.:

NATURE OF PRECIPITATES

The nature of precipitates is, of course, an important factor in determing the degree of clarification achievable by settling. This not only is affected by the precipitant used, but also by conditions under which precipitation occurs, e.g., temperature and the presence of other species. For example:

- When zinc is precipitated at pH 10 or above, the flocs are said to be fluffy and difficult to settle. See Mine-Mill M in Appendix I.

- Cadmium hydroxide flocs are notoriously difficult to settle, and usually a polishing process must be employed (e.g., deep-bed sand filtration) to achieve very low levels. See Lead Smelter B and AMAX Mount Emmons trip reports in Appendix I.

- MgO added as a powder to an effluent is said to precipitate metals effectively and yield a dense, easy to settle precipitate not requiring further clarification.

MIKHNEV, et al. (1978) describe the use of a sulfide solution in $Ca(OH)_2$ to precipitate heavy metals from metallurgical plant effluent. The Cu, Ni, and Fe were precipitated at

pH 5.2, 7, and 7-9 respectively. The degree of removal depended on pH and the composition and dosage of the added $Ca(OH)_2$- $S^=$ solution, and to a very limited extent, on temperature (20-80°C). The treatment at final pH 7.5-8 decreased the metal concentrations as follows:

	Inflow	Outflow
Cu (mg/l)	70	0.1
Ni (mg/l)	80	0.01
Fe (mg/l	10	0.01

The precipitate contained about 12% Cu, 12% Ni, and 20% CaO as CuS, NiS, and $CaSO_4$.

Importantly, the use of $Ca(OH)_2$- $S^=$ solution increased the clarification rate by 50-100%.

CLARIFIERS

Numerous devices are used to clarify solutions. The NALCO (1979) Water Treatment Handbook, Chapter 8, describes several versions typical in the municipal treatment industry where huge volumes of water are treated using very large-scale equipment for coagulation and flocculation which is accomplished in separate operating units, flash mixing for coagulation followed by gentle flocculation mixing. In municipal treatment plants, flocculation is followed by settling and sand filtration.

NALCO (1979) makes the point that the lower the suspended solids content in the process stream or the higher the required effluent clarity, the more critical is mixing to the final results.

There are several clarifier types and approaches to choose from:

- Cylindrical Clarifiers
- Slurry Recirculation Cylindrical Clarifiers
- Hopper Clarifier
- CBI Claricone Clarifier
- AARL-CSIR Cylindro-Conical Clarifier
- Lamella Clarifiers

LAMELLA CLARIFIERS

The capacity of a clarifier is a function of the settling area provided. In this respect, the lamella clarifiers can offer a very much greater effective settling area for a given

floorspace and, except where water is very scaling in nature, this type of clarifier is gaining in popularity.

Lamella or plate-type clarifiers with extensive internal surfaces are less suitable when the solutions are highly scaling. Lamella clarifiers are used in Canada for clarification of effluents after lime precipitation of metals from acid mine drainage and tailings pond decant solution by NORANDA MINES LTD. at Mattabi, Waite-Amulet, and elsewhere. Platepacks are inserted into cylindrical clarifier tanks. The reason platepack lamella clarifiers are preferred be cause of the cold climate making the compactness of lamella clarifiers desirable as the clarifier can then be housed indoors. At two operations, Brunswick Mining at Bathurst, N.B., and the GECO effluent water treatment plant in Ontario,the solutions caused such bad scale that the lamella clarifier proved impractical.

A platepack lamella clarifier that is popular and well backed up in Canada is the PARKSON or AXEL JOHNSON unit offered by:

1

Unobstructed, cross flow characteristic of LINATEX-SERPAC gravity settler. In the patented SERPAC cell suspended solids have, at the very most, only 3.75 cm) to settle before they are out of the primary flow and falling in an isolated sludge chimney zone. This beneficial characteristic of the SERPAC design promotes rapid reduction in the level of suspended solids within the liquid medium as the flow progresses across the cell, creating an optimum condition for settling out of remaining solids. SERPAC design results in more efficient clarification.

Hindered settling characteristic of conventional counter current plate/gravity settler design. Conventional plate (and tube) type "counter current" gravity settlers are not designed for maximum efficiency. Typically, solid particles travel downward through a somewhat turbulent "teeter column" (dimension 'd') during which particles settling out on the plates must travel 183 cm to 305 cm in a downward flow, which is in opposition to the upward rising clarified effluent. Resulting interference and turbulence impede efficiency of clarification process.

2

Removal of metal plates from conventional plate type gravity settler. Other designs of gravity settlers are such that large metal plates and elements must be removed one by one using cranes or other heavy equipment. Moreover, metal components are subject to corrosive attack unless costly stainless steel construction is used.

LINATEX-SERPAC cell is removed as single lightweight assembly. Periodically, it may be desirable to inspect the inside of any gravity settler, and its interior components, to determine their condition. The LINATEX-SERPAC cell construction permits rapid withdrawal of complete cell units from the settling chamber, using a small, inexpensive overhead hoist which can be furnished with the original equipment. Settling chamber interiors are epoxy coated for long service life. For highly corrosive applications, settling chambers can be LINATEX-rubber lined.

3

LINATEX-SERPAC reaction chamber. Flocculent solution is uniformly introduced into feed. Floc formation is promoted and enhanced by controlled centrifugal action and long retention time in large SERPAC reaction chamber. There are no mechanical stirring mechanisms, therefore shear forces are minimized and consumption of flocculent solution is reduced.

Conventional mechanical mixing of flocculating solution and influent. Flocculating tanks, provided with certain other types of gravity settlers, employ mechanical mixing apparatus for the purpose of promoting rapid polymer disbursement and floc formation in relatively small flocculating chambers. Experience has shown that the action of the mechanical mixer blades can break up partially formed flocs, resulting in abnormally high rates of flocculent consumption.

4

Other "package" systems. Some manufacturers sell only a clarifier or gravity settler. The purchaser must determine requirements for all accessory equipment, purchase same from a variety of vendors who assume no unified responsibility for an integrated, functional system. If problems occur, the purchaser must deal with a number of parties, each with limited responsibility and no tie-in to overall system requirements.

LINATEX-SERPAC package system. Each LINATEX-SERPAC water treatment system includes *all* key components required for a fully compatible and functional system. Items normally supplied, in addition to the basic SERPAC cell tank and reaction chamber, include: flocculent mixing and dispensing apparatus, pumps, valves, piping, automatic controls, control panel. All items are selected and manufactured or supplied by Linatex, providing the purchaser with *single source responsibility* for a system to meet proposal specifications.

Untreated influent enters Reaction Chamber at point . Premixed flocculent solution is dispensed from polymer mixing station by metering pump to polymer dilution vessel . Dilution water is introduced to vessel through line . Properly diluted flocculent solution flows from vessel and is injected into influent pipe at . Reagentized influent gently rises in upward spiraling flow within Reaction Chamber, permitting optimum flocculation. Coarser solids present in influent rapidly settle, collecting at lower apex to be periodically discharged by valve , controlled by pneumatic actuator activated by density sensor and powered by compressor . Flocculated influent flows from Reaction Chamber across connector section and enters SERPAC cell(s) through distribution baffle . Suspended solids settle within cell (see page 5 for details), collecting in sludge hopper . Periodically, when sludge is at optimum density, electronic sensor signals air control valve causing the valve to open, thereby discharging sludge into collecting trough below. Clarified effluent discharges from cell through distribution plate exiting via pipe . Control panel provides single point control of all system equipment.

THE SERPAC CLARIFIER

by C.B. PARKER
R.J. Spargo Limited

SYNOPSIS

The Serpac Clarifier is a further development of the thin plate type thickeners and should be considered as tertiary settlers, at the end of the line when clean water is required.

The Serpac system is modular in construction, the flocculent is injected into the feed pipe ahead of the reaction chamber where floc formation is enhanced by gentle centrifugal action and desanding occurs.

A connecting channel to the Serpac settling chamber allows for a non-turbulent stabilised pulp flow. The thin blade settling cell completes the settling of suspended flocs and the water is clarified by a regulating control unit at the discharge end of this cell.

Each Serpac unit has an equivalent of $10m^2$ of settling area and can settle a nominal one ton per hour of solids per module. For efficient clarification suspended solids are limited to ± 3,0% by mass. By using small plastic plates, similar to those used in venetian blinds, a large settling area is generated which is suitable for small flocs containing colloidal and near colloidal solids. The settled sludge is extracted on a timed cycle and the cycle can be controlled by density probes.

Capital cost will vary from ± R600,00 m^3/hr for a single module reducing to ± R215,00 for larger volumes of up to $780m^3$/hr.

Operating costs are in the region of 2,0 cents/m^3.

2. INTRODUCTION

Water is the most commonly used raw material in any industrial process. Upstream it is used as a product constituant, a materials carrier, for washing etc. Downstream it is inevitably a vehicle of industrial refuse; it is this product which is considered in this paper.

Water has mistakenly been considered a cheap material, with rising populations increasing usage, the variability of supply and the rising cost of both for the raw material and sewage surcharges for the treatment of difficult industrial wastes, it becomes more necessary to clean and re-use this water within industrial plants. Considerable water re-use is already practiced and as water reclaimation eventually becomes a cost exercise, the market for reclaimation systems is very cost competitive.

The most common impurity to be removed from water is suspended solids, both non-colloidal and colloidal.

The three important methods are:

i) gravity settling

ii) flotation

iii) filtration

These suspended particles, either in simple or in colloidal suspension, mostly carry a negative surface charge which makes them repulse each other. It is thus necessary to remove or reduce these repulsion charges by the addition

...../2

of positive charged particles using Fe, Aℓ metal hydroxides etc. The second stage is to increase the size of the particles into flocs by agglomeration using long chain high mollecular weight polyelectrolytes.

A third stage comes in with the Serpac, this is artificially multiplying the settling surface by introducing parallel thin bladed plates in order to reduce the floor surface required by the system. The water movement in the Serpac is crosscurrent (see Figure 3).

3. THE MAKEUP OF A SERPAC MODULE

The installation principle is based on an association of components, whose role is clearly defined and optimised, (Figure 1).

3.1. The reaction chamber: Providing -

- the eventual desanding and even some deoiling.
- the coagulation - flocculation reaction with a sludge bed, fluidised at the optimum concentration by the flow of water which leads to a reduction of consumption of flocculating agents.
- an extremely short retention period, 0,5 - 1 minute for quarry muddy water, 1 - 3 minutes for clarification of surface water, whereas 10 - 30 minutes is usually needed.

3.2. A connecting channel between the reaction chamber and the settling tank enabling -

- predecantation without turbulence of the water which comes out of the reaction chamber with up to 50% of the sludge carried by the incoming water already deposited.
- a very stabilised supply adapted specifically to the problem to be solved.

3.3. A thin blade settling cell that -

- completes the settling of the agglomerated suspended microparticles.
- clarifies the water which has been moved by settling and thickening of the sludge. (Figure 2).

3.4. A regulating control unit that -

- regulates the water flow within the cell. The settling is done on clarified water and unlike other thin blade settling modules there is no need for equal distribution of the rate of flow. The pre-settling channel clarifies the upper flow of water very quickly, this arrangement enables the acceleration of the rate of flow in the upper part of the cell, unlike the lower part which works at the normal rate of flow of the thin blade settling tank. (Figure 4).

To enlarge in the principles of the Serpac Cell there are three elements, each making separation easier and more efficient.

1) An upstream reaction chamber for removing the coarser particles.

2) A cell, made up of vertical elements with a certain number of inclined plates, each of the elements being hung on a frame which can support the weight of a man and serve as a grating. Particles slide on the upper side of the thin blade which is at an angle of 60°; when they reach the blade edge they fall into a vertical channel in which the flow of water is stilled by appropriate screens. The particles can therefore, by their density, sink down into the sludge thickener section of the tank, this section will normally be pyramidal. Under the cell vertical baffles are placed in the downhill section to prevent water from running directly under the cell and thus disturb the settlement on the thin blades.

3) A device for recovery of the treated water. This is a perforated tubular spillway which controls the flow of water that can be treated in the cell and is one of the most important elements of the Serpac unit.

It is possible, by increasing the number of stacked blades, to multiply the equivalent surface area of the cell and thus it's capacity for very difficult settling slimes. With the standard 18 blades an equivalent surface of $13m^3$ is obtained (CI Cells). With 27 blades (C2 Cells) an

equivalent surface of $18m^3$ is now available.

The floor area of a cell is approximately $1m^2$.

Advantages of the Serpac

i) Control and optimisation of all the stages in the process.

ii) Reduction of consumption of floculating agents by -

- maximum utilisation of the reaction time
- existance of a fluidised floc forming bed
- smooth transfer of the obtained flocs to the sedimentation zone.

iii) Reduction of floor space occupied by the settling basin as detailed above.

iv) Reduction of the total cell height and thus of the settling tank height compared to other types of thin blade settlers due to the use of cross current flow.

Disadvantages of the Serpac

i) Due to having a low volume ratio to the actual settling area available Serpac is sensitive to changes in the loading rate. It can be advantageous to fit an automatic level/discharge system, especially if the influent solids concentration varies.

ii) Solids content by mass should not exceed 3% for a clean water overflow.

4. COSTS

i) Capital cost can best be expressed for a volume throughput. As the units are modular (each equivalent to $10m^2$ of settling area), a single unit is the most expensive, one would be looking at ± R600,00/m^3/h of flow capacity.

Going up to a 12 cell unit, with a throughput of up to 480 m^3/h then the cost per m^3/h flow drops to R215,00. This is not expensive considering local water costs 23,7 cents/m^3. Using a 4 cell unit, with a 90% recovery and operating 23 hours/day, the payback time is ±714 days.

ii) Reagent costs are difficult to quantify as this depends on the difficulty or ease of flocculation, we have found costs from 0,4 to 5,1 cents/m^3 with 1,8 c/m^3 being a conservative guide figure.

iii) Maintenance costs. These are very low and mainly concern the dosing pump and reagent mixing plus the sludge extraction system. This maintenance cost is likely to be about 20% of the reagent cost.

5. USES

Clarification of industrial waste water from factories, sand washing operations, quarry water, recirculation and cleaning of process water, mill scale separation, separation of metal hydroxides from rinse water in pickling and galvanising plants and final clarification of domestic water.

In the event of the solids content of the influent being too high this can often be sufficiently reduced by using a cluster of hydrocyclones ahead of the Serpac Unit.

Organic materials usually require a completely different treatment.

CONCLUSIONS

Thin plate clarifiers of the Serpac type will have an increasing use in the last stages of reclaiming industrial and mining waters for reuse. As industry expands along with the population growth the demand for water increases, this demand can best be provided by recycling as much water as possible, especially so within the Republic of South Africa where we rely on rainfall to fill manmade storage dams which are subject to high evapourative losses.

ACKNOWLEDGEMENTS

This paper is presented with the permission of Mr. S.H. Spargo, Chairman of R.J. Spargo Limited. The author thanks ERPAC of Wasquehal, France for their technical assistance.

FIG. 1

The Serpac Cell

The Serpac Cell (Erpac patent

Flowing in the direction of th arrow (A) the water to be treat ed runs horizontally throug the cell. Under separation for ces, the particles move ver tically in the water flow unti they touch the cell blades (1 then they slide along the blade and are drained away throug the sludge collecting funnels (2 where transverse baffles (3 prevent internal circulation.

Fig. 3 -
Settling by cross flow feed

Fig. 4

Crossflow decanters - Type Serpac

The water circulates in each decanter element between two parallel blades with angle to the horizontal. The slurry decants on the lower blade and slides due to the inclination and then falls into the passage CB to enter the thickener section. The water displaced by the slurry in the thickener comes up through a passage and is clarified in channel CE. The filters E obstruct the raw water circulation and cause the water displaced in the slurry to ascent vertically.

APPENDIX 1

The three types of settling process on thin blades

The HAZEN formula defines the climbing velocity as the quotient of the rate of flow treated on the mirror surface : Q/S. The equivalent surface of separation S is the product of the projected surface of the rectangular blade L.I. on a horizontal plane by the number of blades N in service; it formulates itself:

$$S = N\ (L.I.\ \cos.\alpha) \qquad \text{(Fig. 1)}$$

Co-current supply, supply by reversed current, these devices suffer from inadequacies. They led the test department ERPAC to experiment and improve the third type of supply known as "cross currents". With this system, the effluent must not pass once again through the sludge screen and particles can be eliminated from the plates and will settle out according to an oblique trajectory. Moreover, this choice is justified by the useful length of the plates. The theoretic calculation of the length of the necessary distance between two plates for a same space e, a same length l, a settling velocity Vs and a laminar flow Ve shows the advantage of the supply by cross currents (Fig. 2b).

By reversed current, the time needed to cover $P_E P_S$ is equivalent to:

$$t = \frac{e}{V_S \cos \alpha}$$

The length L will then have to be:

$$L = (VE - V_S \sin \alpha) \frac{e}{V_S \cos \alpha}$$

.....cont

By co-current under the same conditions, we obtain:

$$t = \frac{e}{V_S \cos \alpha}$$

relative to a distance :

$$L = (VE + V_S \sin \alpha) \frac{e}{V_S \cos \alpha}$$

Whereas by cross currents, we have :

$$t = \frac{e}{V_S} \quad \text{et} \quad L = \frac{VEe}{V_S}$$

As a consequence, the length L will be shorter in a thin plate settling basin with cross currents because α and $\sin \alpha = 0$, $\cos \alpha = 1$.

The thin plate settling tank by counter current would have to be slightly shorter than the system by co-current for a same value of α but in practice, the difference affects only by a few percentages the value of L. Ve ranging between 30 and 100 m/h, V_S varying between 0,5 and 5 m/h.

advantages when compared to conventional clarifiers

A LINATEX-SERPAC system usually offers a number of significant advantages without sacrifice of efficiency when compared to conventional tank type thickeners. These are:

SERPAC systems require very little maintenance or adjustment. The lightweight, plastic SERPAC cells are corrosion proof. Unlike a conventional tank type clarifier, there are no troublesome rake mechanisms, no mechanical drives to maintain, no moving bridge-work. There are *no* moving parts in the SERPAC settler.

The installed cost of a SERPAC system is, in almost every case, considerably lower than the cost for a conventional thickener-clarifier. Installation of a SERPAC system requires only simple foundations: no expensive excavation, no underground sludge pumps and tunnels, no complex erection stages. Units are shipped semi-assembled from our factory and erection can be accomplished in a matter of days, not several months as is commonly the case with conventional tank type clarifiers.

SERPAC plants occupy only a fraction of the space required for the installation of a conventional circular tank thickener-clarifier. In many cases the space requirement can be reduced by as much as 90%. Such a consideration may be very important if the clarifier is to be installed in mountainous terrain or housed in a building.

ESSENTIALLY HORIZONTAL TUBE SETTLER

STEEPLY INCLINED TUBE SETTLER

The basic tube settler configurations used with flocculation and filtration. *Neptune Microflloc, Inc.)*

CYLINDRICAL CLARIFIERS

Various configurations of cylindrical clarifiers as illustrated in NALCO (1979) are shown below. There are numerous suppliers of cylindrical clarifiers serving each industry center.

CYLINDRO CONICAL SETTLERS

In the U.S.A., CHICAGO BRIDGE AND IRON, Walker Process Division, offers a cone settler which they call a claricone clarifier. This is no more than a conical tank into which feedwater is introduced tangentially with flocculant addition allowing a sludge banket to build up. There are also internal skirts and baffling. The claricone clarifier is said to be an expensive version of the "Hopper Clarifier" of which several versions are installed on Witwatersrand gold and uranium mills where they are constructed by the mine maintenance staff using the basic Pachuca design as the shell.

"Hopper Clarifier"

The first "Hopper Clarifier" on the Witwatersrand was installed at Vaal Reefs South to preclarify pregnant gold solution ahead of a Stellar filter in the Merrill-Crowe Zinc precipitation section of the gold mill. This described by KUN, et al. (1979). More information is included in trip reports on Vaal Reefs in RANDOL (1982, 1983). A critical feature of the operation of the Hopper clarifier is that an adequate flow velocity must be maintained to keep the sludge bed suspended. The minimum flow velocity is 7 m/h and, at Vaal Reefs, it is maintained at 7-9 m/h and a pH of 10.8-11.2. CYANAMID Superfloc N100 non-ionic flocculant at 0.1% concentration is dosed to the bottom of the conical bottomed clarifier at 0.2 g/t through a separate feed line by a mono pump.

The required energy for coagulation is supplied by the feed velocity into the apex of the cone at 1.8 m/s flow velocity in the feed pipe.

The advantages of the Hopper Clarifier are several:

1. Trouble-Free Operation
2. Easy to Operate Requiring Almost No Operator Attention
3. Very Inexpensive
4. Simple Design, Easy to Install at a Low Capital Cost

More information can be obtained about the Hopper Clarifier through:

W. A. KRETSCHMER
Manager Metallurgical
Vaal Reefs Exploration and Mining Co. Ltd.
Post Office Box 5010
Vaal Reefs 2621
South Africa
(018) 7141

Eddie Van Vuuren, a former metallurgical manager of Vaal Reefs who was actively involved in the development and installation of the Hopper Clarifier at Vaal Reefs South may also be able to provide an insight into its design and operation as a consulting service:

HOPPER CLARIFIER VAAL REEFS

E. J. J. VAN VUUREN
Metropolitan Rand Projects (Pty) Ltd.
Post Office Box 32068
Braamfontein 2017
South Africa
(011) 836-2075

Variations of the "Hopper Clarifier" have subsequently been installed on several gold and uranium mills on the Witwatersrand. These include GOLD FIELDS OF SOUTH AFRICA LTD., at Deelkraal, RANDFONTEIN ESTATES G.M. CO. LTD. (JCI) at Cooke Plant, and GENCOR LTD. at Buffelsfontein, where a REUNERT & LENZ deep cone circulator clarifier has been installed.

At RANDFONTEIN ESTATES, a Vaal Reefs-type Hopper Clarifier has been installed to clarify acid uranium leach filtrates with excellent results--apparently, it works so well that no further polishing of the solution is needed before it can be sent to the solvent extraction step for uranium recovery. More information can be requested through:

JOHANNESBURG CONSOLIDATED

Consulting Engineer (Metallurgical)
(011) 836-2571

At BUFFELSFONTEIN GOLD MINING CO. LTD., the REUNERT & LENZ deep cone hopper clarifier reduces suspended solids from 500 mg/l in the feed to 10 mg/l in a single stage. It is said to differ slightly from the ANGLO AMERICAN hopper clarifier in that its internals are not quite the same. The The unit tested at BUFFELSFONTEIN G.M. CO. LTD. was a pilot unit which treats 10 m^3/hr. Also, REUNERT & LENZ are said to have an excellent lab scale demonstration of the system. The person to contact from which to find out about this unit is:

PIETER VAN ASWEGEN
Gencor Ltd.
Box 1820
Marshalltown 2107

HUNTER & EMERE (1977) described the use of cylindro-conical settlers for underground minewater clarification at the Harmony Gold Mine, but this would refer to data prior to the Anglo American Research Laboratory improvements to the system.

DISPERSED AND DISSOLVED AIR FLOTATION

For acid mine drainage and metallurgical solutions containing very small suspended solids loadings and also for solutions or wastewater containing oils and grease (often in

saponified colloidal suspension), cutting oils, or emulsified solvent extraction organics, DAF may well prove to be the most practical and effective approach. DAF can refer to dissolved air flotation or dispersed air flotation.

DAF: REXNORD ENVIREX DIVISION

Dispersed air flotation was tested, reputedly with excellent results, alongside the DRAVO electroclear coagulation and flotation system installed at AMAX's Climax Molybdenum Mine effluent treatment plant and at their Mount Emmons water treatment plant, Crested Butte, both in Colorado. The Mount Emmons facility is described in Appendix I.

Because both AMAX plants are already running well using the DRAVO Lectroclear process for metal precipitate sludge recovery, it is not likely that it would be cost effective to replace a system that already works well with another that works marginally better. However, AMAX is said to have found the ENVIREX DAF system as being one of the best they could find from among DAF equipment suppliers.

SERFLO EFFLUENT WATER TREATMENT SYSTEM

NOTE:
The purpose of this illustration and description is to indicate the general method employed. Each application requires separate consideration based on the desired results and the characteristics of the effluent to be treated as disclosed by laboratory tests.

Numerous features of the SERFLO System are covered by patents in Great Britain and other countries.

A. The flocculating reagent is prepared and metered into the untreated feed by a dosing pump. A coagulant or other reagent is also added if required.

B. The treated feed is conditioned in a reaction chamber the purpose of which is to encourage the formation of stable and well formed flocs. At the base of the reaction chamber a drain is provided to enable any heavy solids present to be removed.

C. From the reaction chamber the flocs in suspension pass to the entry chamber of the Serflo Tank.

D. In the main section of the tank the introduction of dissolved air causes the flocs to float to the surface. The dissolved air stream is dispersed over the complete width of the tank and moves in a horizontal direction. This forms a parallel layer below the floc laden material being treated.

E. As the solids reach the surface they are removed by the slow moving chain driven scraper gear.

F. The efficiency of flotation is improved by means of the patented Serflo cell.

Table of Capacities and Dimensions Height required 2,3 metres. For servicing allow 3 metres.

Standard Modules	Capacity m³/hr	Floor Space Dimensions
Serflo 1.	20 to 40	4,0 x 5,2
Serflo 2.	40 to 60	5,5 x 5,5
Serflo 3.	[illegible] 120	6,7 x 6,2
Serflo 4.	80 to 160	8,5 x 7,9
Serflo 5.	100 to 200	10,0 x 6,3
Serflo 6A.	120 to 240	10,0 x 7,2
Serflo 6B.	120 to 240	9,0 x 8,5

G. Clarified water passes a specially designed weir plate to be discharged.

H. Clarified water, drawn from the tank adjacent to the point of discharge, is pumped to the pressurisation unit where air is dissolved under pressure and later released at three separate points in the Serflo tank to form curtains of minute air bubbles.

J. A control panel is provided which incorporates control gear for the mixing of the reagents, the scraper gear, the pressurisation unit and in most instances, the pump feeding the system but not shown in the illustration.

K. The scraper gear conveys the recovered solids up a ramp and discharges them from the system.

FLOAT-TREAT SEPARATOR

FOR STEEL OR CONCRETE TANKS

Rex Float-Treat Tanks employ proven principles of tank design assuring optimum use of tank volume. Inlet piping, reaction jets, inlet and effluent baffles provide positive, thorough distribution and dispersion with carefully controlled flow patterns for maximum clarification, flotation and settling.

The many advantages of Rex Float-Treat Separators may be obtained with either steel or concrete tanks, in single or multiple units. Steel tanks are available as "packaged duty" units shipped complete, ready for simple piping and wiring on installation.

Existing gravity settling tanks can often be converted economically to Float-Treat. Existing sludge-handling equipment may also be used with slight modifications.

Correct pressure is maintained by either automatic or manual controls to assure efficient operations under all flow conditions.

with accurately formed beach assures a relatively dry scum and clean discharge.

Rex Scum Removers are available in a wide variety of types and sizes. Proper materials are available for unusual corrosive conditions, explosive atmospheres, etc.

Proper amount of air is fed directly into the pressure tank for optimum saturation. Air feed is regulated by the pressure tank liquid level controller and a solenoid valve in the air line.

prevents floatable solids from passing out of tank . . . directs clarified effluent to outfall weir.

assures uniform discharge and controls water level in tank for optimum skimming conditions.

integral with Float-Treat tank, provides a continuous supply of treated effluent for recycle system even though raw flow may be interrupted.

withdraws portion of effluent and pumps it to pressure tank. Because only a small portion of effluent is recycled, pump size and pumping costs are held to the minimum.

is designed and tested to conform to rigid code requirements. Positive liquid level control assures maximum saturation of pressurized flow. Tank may be supplied with or without packing as conditions warrant.

is obtained by any of several types of conveyors . . . from screw conveyors in smaller tanks up to heavy-duty conveyor sludge collectors for the larger projects.

Raw flow and recycle stream enter the Float-Treat Tank through the inlet manifold. As the blended stream enters, it impinges on concave reaction baffles for thorough diffusion throughout width and depth of tank. Inlet piping and reaction jets are carefully sized and located for correct velocities, proper bubble formation and thorough blending.

Pressurized recycle liquid is introduced into raw flow line immediately downstream from pressure reduction valve.

TRICELLERATOR DAF FOR LOW-DENSITY ACID MINE DRAINAGE PRECIPITATE REMOVAL

BOSMAN (1983) demonstrated that dissolved air flotation is an attractive alternative means of solids/liquid separation to gravity settling for water producing relatively small amounts of sludge on lime precipitation (100 to 200 mg solids per litre). At hydraulic loadings of 7 m^3/m^2 h (seven times higher than gravity settling), the flotation process produced an effluent containing less than 15 mg/l suspended matter and a sludge with a density of 50 g/l (5% solids). The case that was tested was neutralized acid mine drainage from a coal mine at Vryheid Coronation Ltd. in Natal, South Africa, one of the mines in the ANGLO AMERICAN CORPORATION GROUP.

Based on these tests completed in 1981, a plant to remove precipitate from 1,200 m^3/day of neutralized acid mine drainage was estimated to cost about R90,000 ($45,000).

Normal operating pressures in the vessels used to supersaturate feed solution with air for the DAF process is around 400 kPa. Once saturated with air under pressure, the water is fed into the inlet stream of the flotation unit, and the air comes out of solution as a cloud of minute bubbles. These bubbles then lift suspended solids in the form of a sludge to the water surface where it is scraped off mechanically. DAF can also be performed in a somewhat simplified version of the process. Instead of using an air compressor and pressure vessel, the "Tricellerator" uses high pressure water pumps to dissolve air in water. The pumps, usually three per unit, draw water from the bottom of a cylindrical cell, entraining air into the stream by means of a hydraulic ejector. Under the turbulent and pressurized conditions in the pump, the entrained air becomes dissolved in the water and, on being discharged into the cell and consequent release of pressure, comes out of solution as fine bubbles.

The concentration of air dissolved in the water is not as high in this system as in systems using optimum saturation conditions. However, the process achieves similar air to solids ratios by operating at larger recycle ratios.

When laboratory-scale DAF tests indicated benefits in effluent clarity, sludge density and possibly plant capital costs over gravity settling of solids for treating Coronation Vryheid mine drainage, pilot tests were conducted with the smallest size of "Tricellerator" available. The unit was rated by its suppliers at 11 m^3/h. The results of the tests showed that consistent with acceptable sludge density and effluent clarity, the plant was capable of athroughput of 18 m^3/h which is 160% of the supplier's design capacity and which represents a hydraulic loading of about 7 $m^3/m^2/h$. Since gravity settling can seldom be conducted at loadings of more than 1 $m^3/m^2/h$, the flotation cell may be substantially more compact than a settler for gravity settling for treatment of the same water. The sludge density of 50 g/l produced in this test means that the DAF sludge volume would be only 20% of that obtained by gravity settling and 2.5 times more than the

volume generated by the HDS process. However, since the amount of solids in this water is so low to begin with, the 2.5 l of sludge per m^3 water treated would not present a major disposal problem.

The brief ANGLO AMERICAN RESEARCH LABORATORIES' tests at Coronation Vryheid revealed that proper flocculation of the suspended solids was the key to successful operation of the plant. The flocculation stage of the pilot plant consisted of the addition of lime to the acid water under conditions of vigorous stirring to pH 9 (the same coagulation may have been achieved at pH 7 with the aid of alum, but the former method was chosen for simplicity). The water was then passed through a pipe with a retention time of 4 minutes at a velocity of about 0.3 m/s followed by a dosage of polyelectrolyte (0.5 mg/l of nonionic polyacrylamide proved optimal) injected directly into the inlet to the "tricellerator."

In the pilot test, the best sludge density was achieved by allowing a float to build up undisturbed for 25-30 minutes before removing it during a 2-5 minute period of scraping with the scraper arm rotating at about 2 rpm.

The following results were achieved in the pilot test:

	Raw Water	Effluent Water	Sludge
pH	6.7	9.0	
Total Iron	30 mg/l	LT 1 mg/l	
Suspended Solids	46 mg/l	LT 15 mg/l	5.3%

The approximate 1981 cost of a tricellerator clarification unit treating 1,200 m^3/d was 20% less than a comparable gravity settling plant.

Mechanical Equipment Including Electrical Controls, pH Control, Steelwork, etc.	R75,000
Civil Engineering:	
12 m x 6 m x 200 mm Slab (Reinforced)	R4,000
Room 4 m x 5 m Chemical Storage and Makeup	R5,000
Contingencies	R6,000
	$90,000

In the end, it was found that a waste treatment plant was not required because the flow of acid mine drainage stopped before the plant could be constructed.

FIGURE III. SUGGESTED LAYOUT OF PROPOSED FULL SCALE PLANT

SCALE: APPROXIMATELY 1:50

TRICELLORATOR

The Tricellorator operates on the principle of dissolving gas in a liquid under pressure, but not with the use of a gas contacting tower. This device takes advantage of high speed pumps to disperse the gas and collapse the bubbles by pressure on the discharge side of the pump. The water or liquid is pumped three times and unlike conventional flotation cells the discharge is confined to a relatively small area. This is accomplished by dividing the tank into three equal parts or four in the design of larger systems. Each section confines the gas rise so that a scrubbing action is achieved. This action accounts for the high percentage removal of both oil and solids. Tests show residual oil less than 10 PPM without chemical dosage.

Incoming water may be pumped or it may flow into the Tricellorator by gravity. In any event the incoming liquid is not pressurized beyond normal pumping practice. The first stage only takes suction from itself and returns water to itself. Number two and three pumps take suction from the preceeding stages. Clarified water is removed from the last stage by a riser tube connected to an adjustable weir box.

The surface of the Tricellorator may be skimmed in a conventional manner with a single paddle discharging recovered float into a recovery chute. Where water may be tolerated with the recovered oil, skimming may be by gravity with adjustable weirs in each sector. The Tricellorator may also be skimmed by a Continuous Belt Skimmer where it is desired to have minimum water in the recovered oil.

Gas or air may be used as a flotation media. Where it is desired to maintain anaerobic conditions than Methane should be injected. In all cases the gas (air) must be injected on the suction side of the pumps and through a premixing system that reduces the possibility of gas locking. Units are available in sizes from 50 GPM through 2,000 GPM. Please see drawing D-406. Patent applied for.

PRECIPITATE FLOTATION OF IRON-CYANIDE COMPLEXES

According to BUSCH, et al. (1980), ion precipitate flotation was tested as a means of removing cyanide in the form $Fe(CN)_6^{-4}$ and $Fe(CN)_6^{3-}$ from wastewater from plating and mineral processing. Preliminary tests indicated that this process has good potential for the removal of ferrocyanide and ferricyanide complex ions. Free ions are extracted but do not float as well as the Fe-cyanide complexes. The removal of Fe-cyanide complexes increases with addition of a surfactant, i.e., tricaprylmethylammonium chloride in a dose of no more than 1.25 times the stoichiometric amount and decreases with increased surfactant dose. The removal of these complexes is satisfactory at the air flow rate of 3 l/mm and pH 4-10. After the Fe-cyanide complexes have combined with the surfactant, they float equally well.

   Englewood, CO 80112
   (303) 779-5331
   John Whellock
   Dave Robinson

3. SHIMOIIZAKA and MATSOUKA (1976) reported the use of dissolved air flotation for removal and recovery of Cu and Cd precipitated by lime or sulfide ions from solution.

4. KAIDA, et al. (1978) reported the use of air oxidation of Fe^{2+} catalyzed by $NaNO_2$ fractional precipitation of $Fe(OH)_3$, neutralizing coagulation, and sedimentation followed by flotation separation and sludge treatment The concentration of heavy metals in the effluent was reduced from 549 ppm to 0.91 ppm to 0.91 ppm for Zn, and 4.92 to 0.04 ppm Cd. Fe and Cu were not detected in the treated effluent.

5. In Bulgaria, the selective recovery of cobalt from aqueous sulfuric acid solution was tested by selective solvent extraction followed by flotation of the organic phase. Zn, As, and Pb ions in the clear aqueous solution were then precipitated as hydroxides by lime addition. This was tested on waste water from the wet scrubbers at the G. Dimitrov Mining and Metallurgical Plant in the city of Eliseina.

6. BENCKE, et al. (1981) showed that Cr^{3+} can be effectively removed from metallurgical wastewaters by coagulation and dissolved air flotation. DAF resulted in more effective and faster clarification and a greater solids content in the sludge than could be achieved by settling. pH of the solution, formation of $Cr(OH)_3$ flocs, and the type of wastewater influenced the degree of clarification. Although $Cr^{3=}$ can be removed from suspension, it is not clear to what levels the precipitate can be

removed. The authors can be tracked down through the following incomplete address:

SONIA BENCKE
Dept. Eng. Quimica

ELECTROFLOTATION OF PRECIPITATES

Electroflotation is identical to DAF in principle, except that in electroflotation, gas bubbles are generated electrolytically. The disadvantages are that hydrogen gas is generated and secondly, unless the electrodes are made from expensive alloys, they tend to be corroded and require periodic replacement. In oil flotation, electrodes tend to become coated and passivated.

The only commercial units known for electroflotation are those offered by Dravo, known as Lectroclear. These have been installed in numerous meat packing operations for water treatment where the process was known as the SWIFT Lectroclear process until it was acquired by DRAVO CORPORATION.

Although several Lectroclear flotation units are installed for a variety of clarification purposes--e.g., recovery of suspensions of drilling muds in wastewater--only two are known in a minewater-mill effluent environment. These are at the Mount Emmons water treatment plant of AMAX, Inc., near Crested Butte and at the mill tailings effluent treatment plant of CLIMAX MOLYBDENUM, INC. at Climax, Colorado.

The two Colorado clarification systems remove base metal and iron hydroxide precipitates from an effluent stream located at high altitudes where water temperatures are at or close to 4°C' for much of the year. The systems are described in a trip report on Mount Emmons in Appendix I. They were selected because at the time, Lectroclear was the only system that had been demonstrated to work well on cold, high viscosity water. In the meantime, other methods of removing suspended precipitates have been demonstrated at these sites--namely, dissolved air flotation.

The Mount Emmons treatment plant treats an average flow of 400 U.S. gpm (2,200 m^3/d) but is designed to treat up to 11,000 m^3/d during the spring runoff. The plant cost around $10.9 million to install, and annual operating costs are around $750,000.

After electrocoagulation and Lectroclear flotation of suspended precipitates, the water is filtered through two Dravo deep-beed sand filters to achieve very clean water with very low base metal contaminant levels and 5 mg/l suspended solids. The Lectroclear flotation units remove 98% of the suspended solids at 700 ppm solids feed level. Allied Colloids' Percol 728 (a cationic polymer) is used for final sludge dewatering ahead of the belt presses, but Nalco 8815 at 1.5-3.5 ppm is used for coagulation and 1-3 ppm Percol 278 cationic polymer is added ahead of the flotation cells. The sludge as skimmed from the cells contains 2-3% solids, but this is increased to 12% using belt presses.

RAMIREZ (1981) described the use of electroflotation for removal of Group IV-A heavy metals from mine tailings wastewater.

Details on the Dravo Lectroclear Flotation System is available from:

SETTLINC AND POLISHING PONDS

Settling and polishing ponds are generally more effective for the removal of coarser suspended solids and denser materials than base metal precipitate sludges.

Onaping

In the trip report on Falconbridge's Onaping mine-mill complex in Ontario in Appendix II, it is noted that a large lake is effectively used to polish solutions after addition of a ground limestone slurry for pH adjustment of tailings decant solutions. This works effectively. There apears also to be some kind of biological nickel removal effect in the pond, but this has not been defined.

Also, in the same trip report, reference is made to the treatment of minewater from the Onaping Mine by addition of sodium hydroxide solution to the feedline to precipitate nickel as nickel hydroxide. The neutralized minewater representing a small flow is settled in a small pond which is fitted with a berm baffle to discourage short circuited flow and allow longer residence time for settling. The $Ni(OH)_2$ precipitate settles effectively in

this arrangement forming a sludge on the bottom of the pond containing 5-10% Ni. This is where a problem arises.

Mine sewage in small volumes is also dumped into the same pond. Due to biological degradation of sewage, much of which settles to the bottom of the pond, methane gas is generated which in turn attaches itself as bubbles to the precipitate. The result is that 5% Ni precipitate particles are being floated, and these escape with the pond overflow to the main solution polishing lake. Even though the floating precipitate is diluted in the main pond, it certainly would not take much to give a high reading if it happened to be collected in a final effluent sample.

Settling ponds are in standard use in placer gold recovery operations. As mentioned above, these streamside ponds lend themselves to the use of Hercofloc gel flocculant logs to make them more efficient.

It is common practice to compute a nominal residence time in such ponds by dividing the total volume by the influent flow rate. This has often been found to be an overestimate of actual residence time because where a pond has an inlet and an outlet, there will almost certainly be short circuiting. First, surface waters do not mix with deeper waters which may be stratified due to temperature or concentration effects. Second, channelling of surface water flow from the inlet to the outlet does typically occur. Actual residence time of water in a pond may be as low as 10% of that calculated by dividing total volume by flow rate.

An important application for settling ponds is, for example, as a primary treatment in plant runoff water to settle out concentrate particles. These particles are dense and settle readily but if not removed, will settle elsewhere in the system where they oxidize over a period of time and add metal ions to solution. At Falconbridge's Falconbridge operation, plant runoff water was collected in a small lake and decanted. Over the years, the oxidizing mineral particles generated soluble metals which started contaminating local wellwater used as potable water in the plant. The problem was solved by dredging the lakebed and processing the material through the mill to recover values worth $1.5 million. Another example is at St. Joe Minerals' Edwards Mill at Balmat, New York, where runoff water was allowed to settle in a shallow pond, and significant quantities of mineral value were trapped over a period of time. This pond, now dry, is illustrated below.

SETTLING POND TRAPS CONCENTRATE IN MILLSITE RUN-OFF

BIOLOGICAL POLISHING POND - FALCONBRIDGE, ONTARIO

BIOLOGICAL SYSTEMS

Biologically active ponds can be very effective at removing suspended particles from effluents. They can also have the reverse effect. It was shown above how, in a small pond at the Onaping Mine, biological degradation of sewage resulted in the flotation of a nickel hydroxide sludge from the pond bottom which was then discharging at the pond outlet.

At Falconbridge's operation at Falconbridge, Ontario, mill tailings decant solution containing metals is neutralized, and metals are precipitated by lime addition. The neutralized solution discharges from the aeration/lime addition plant to a settling basin and from there into a huge swamp area covering 2-3,000 acres which supports a prolific growth of cattails and a host of other species including large underwater algae populations. The algae and plants offer a huge surface area onto which the precipitate particles can and do attach themselves. Water discharging from the far end of the pond has a low suspended solids content. If the pond is large enough and if the biomass is great enough, the suspended metal precipitate load will be "metabolized" by such ponds. Decaying biomass at deeper levels on the pond bottom release enough marshgas H_2S to convert the hydroxides to sulfides which will then settle to the bottom of the marsh and accumulate. This phenomenon has been observed by Dr. R. L. Kleinman at the Bureau of Mines in his studies of acid mine drainage abatement.

Biological ponds have also been observed by Jennet as reported in WIXSON (1977) to reduce organics contained in mine-mill effluents. Presumably, much of the organics measured are colloidal oil and grease from the mining operation and possibly some flotation reagents. Algae in the meander system installed at a lead-zinc mine in Missouri resulted in a marked decrease in the levels of organics in water that passed through the ponds.

Further information on this phenomenon as well as metals polishing in the meander system containing algae could be discussed with:

An interesting phenomenon pointed out by Dr. Wixson is that when metal precipitates or organics from flotation plants are present in a pond, algal mats are likely to form due to enhanced growth of algae (perhaps stimulated by the contaminants?). During periods of flooding, these can break loose and become distributed downstream and, in that way, also distributing metal values. For this reason, both the mine-mill complexes in Missouri that installed meander systems for algae growth also installed final polishing ponds to trap any algae that break loose.

In New York state, St. Joe Resources at their Pierrepont mine have constructed a meander pond to encourage plant and algae growth as a means of polishing minewater before final discharge. At the time of the Randol 1984 visit, this system had just been constructed, and the plants had not yet properly established themselves, so it was too soon for performance data. MULTI-MEDIA AND DEEP-BED FILTERS

Low suspended solids (say, 1-8 ppm) can be achieved using multi-media or deep-bed filtration. This type of equipment is generally required to meet permit requirements for effluent discharge, not only with respect to suspended solids, but also heavy metals. Even if base and heavy metals, arsenic, etc. have been precipitated, they are unlikely to have been removed to the levels required by typical U.S. effluent discharge permits in the primary settling or flotation process. This is where a polishing filter is required. Usually, the solids load in the precipitated effluent is too high for a sand filter to be used as a primary sludge removal process, but these filters do work well as a polishing step.

Several types of polishing filters were observed in various water treatment plants at mines and mills visited.

AMAX, Mount Emmons

Four 12' 6" Ø 16' 4" deep Dravo multi-media sand filters are installed as a polishing step at the Mount Emmons water treatment plant, Crested Butte, Colorado. Several grades of sand and gravel are loaded into these downflow filters as described in the trip report in Appendix I. The bulk of the media is made up of 1-2 mm graded silica filter media. The other fractions are gravel in various sizes grading from 1 1/2" x 3/4" to 1/4" x 1/8" silica gel. Since startup in 1980/1981, the media has never had to be replaced although, occasionally, mudballs are removed from the surface of the filters.

DRAVO CORP. markets an innovative and effective deep-bed sand filter system. The units at Mount Emmons are open gravity flow units, but Dravo also offers a pressurized system. Advantages calimed for the DRAVO deep-bed system are:

- High Filtration Efficiency
- High Specific Loadings; from 1.0-10.0 lbs. of suspended solids removed per ft^2 of filter area (time?).
- Heavy Duty Backwash
- Compactness; it requires 50% or less of the area needed for other types of clarification processes.
- Simplicity of Operation; usually no pumps are required for pressure operation.
- Easily Designed for Fully Automatic Operation
- Low Backwash Water Requirements
- Low Media Attrition - Less than 1% per Year
- Low Operating Costs

The vendor claims that suspended solids can be reduced to 1.0 ppm or less using these filters.

Information on Dravo deep-bed filters can be obatined from:

DRAVO RECOVERY SYSTEMS
Manufacturing Development Center
222 Third Street
Neville Island, PA 15225
(412) 777-5241

Other locations where deep-bed sand filters or multi-media filters are installed for final polishing of effluents after precipitated metals have been removed by conventional settler-clarifiers are at INCO LTD.'s Copper Cliff water treatment plant, Sudbury, Ontario, and at ST. JOE RESOURCES CORP. at Monaca, Pennsylvania, where effluents from their zinc smelter/refinery are treated for discharge. In Appendix I, a lead smelter is described where an attempt to remove metal precipitates from an effluent by a clarifier alone does not produce final effluent that meets their discharge criteria for much of the time.

Deep-bed sand filters are standard items in water treatment, and there are numerous suppliers to choose from. One supplier who believes he has developed an improved system is:

NEPTUNE MICROFLOC, INC.
Box 612
Corvallis, OR 97339

DYNASAND FILTER

A brochure describing the DYNASAND filter made by AXEL JOHNSON is inserted below. This device is very practical because it continuously recirculates the sand media to remove particles of suspended solids that would otherwise clog the surface. More details on this most innovative device can be obtained from:

A NEW Concept In Sand Filtration

Continuous Sand Filtration

The DynaSand Filter is a continuous backwash, upflow, deep bed granular media filter. The filter media is continuously cleaned by recycling the sand internally through an airlift pipe and sand washer. The regenerated sand is redistributed (right) on top of the sand bed allowing for a continuous uninterrupted flow of filtrate and reject water.

Feed is introduced into the bottom of the filter, then flows upward through a series of riser tubes and is evenly distributed into the sand bed through the open bottom of an inlet distribution hood (A) (Fig. 1). The influent flows upward through the downward moving sand bed (B) with the solids being removed. The clean filtrate exits from the sand bed, overflows a weir (C) and is discharged from the filter (D). Simultaneously, the sand bed, along with the accumulated solids, is drawn downward into the suction of an airlift pipe (see Fig. 2) which is positioned in the center of the filter. A small volume of compressed air is introduced into the bottom of the airlift (E). The sand, dirt, and water are transported upward through the pipe at a rate of about 200 gpm/ft². The impurities are scoured loose from the sand during this violently turbulent upward flow. Upon reaching the top of the airlift (F), the dirty slurry spills over into the central reject compartment (I). The sand is returned to the sand bed through the gravity washer/separator (G) which allows the fast settling sand to penetrate, but not the dirty liquid. The washer/separator is placed concentrically around the upper part of the airlift and consists of several stages to prevent short circuiting (Fig. 3). By setting the filtrate weir (C) above the reject weir (J) a steady stream of clean filtrate flows upward, countercurrent to the sand, through this washer section and acts as a liquid barrier that carries away the dirt and reject water (K). Since the sand has a higher settling velocity than the dirt particles, it is not carried out of the filter. The sand is redistributed by the means of a sand distribution cone (H). The sand bed is continuously cleaned while both a continuous filtrate and a continuous reject stream are produced.

DYNASAND® FILTER

Multiple units can be installed and still maintain system simplicity (top photo). The pressure drop across the sand bed insures an even feed to each filter without the need for splitter boxes. A header pipe with the appropriate number of Tee Connections is all that is required.

For large flow applications, our concrete basin design consisting of multiple cells is available. Cells can be custom arranged to fit individual plant configurations. The concrete designs are particularly well suited for large flow surface water and tertiary filtration applications. (Bottom photo).

All equipment described in this brochure is protected by patents, and additional patents may be pending.

Advantages: DynaSand® Filter Vs. Conventional Filtration Designs

Continuous Operation
No need to shut down filters for backwash cycles

Elimination of Auxiliary Equipment
There is no need for backwash tanks, pumps, valves, instrumentation, etc.

Simplicity
No moving parts — no operator attention required.

High Solids Capability
Can handle up to 800 ppm solids in the influent for some applications

Low Pressure Drop
Less than 24" pressure drop — easy to gravity feed

Low Power Consumption
Gravity feed or low pressure feed pump and small air compressor are all that is required.

Single Media
No need for internal screens, grids, underdrains, etc.

Continuously Cleaned Sand Bed
No mudball formation

No need for Continuous Chlorination

Improved surface loading rates where the loading rates are limited by solids capacity.

No requirement for flow control valves or splitter box arrangements

* Includes handrail and platform

High Efficiency/Low Energy—Because of the efficiency of this backwash system, air and water requirements are low, usually about 6 scfm of air and 6-8 gpm of water per square foot of filter surface area. Total backwash water consumption usually is about 150 gallons per square foot of filter surface area for each backwash cycle. This small requirement allows backwash to be supplied from a standpipe in the filtrate header on pressure plants. In all cases, the size of pumps, piping, valves and storage tanks in the backwash water supply system and in the dirty backwash water disposal system can be smaller with the Dravo Filter system than with other types.

Instrumentation— The standard instrumentation for Dravo Deep-Bed Filters incorporates the latest Programmable Logic Control for unattended automatic operation. Primary backwash initiation is based on time, with system differential pressure and operator manual initiation overriding.

In addition to a main control panel, local panels are provided on large installations allowing the operator to monitor, inspect and maintain the filters from the filter plant floor.

Pressure or Gravity Operation— The Dravo Deep-Bed Filter System is available for pressure or gravity operation. The proper selection depends upon hydraulics, economics, available space and energy requirements of the total system.

Media Selection— The Dravo Filter can accommodate a variety of media types, sizes and depths. Each application is analyzed carefully and the proper media is selected to optimize the system's design.

Flow Rate— For industrial wastewater applications, a deep bed of specially selected filter media which permits high filter flow rates in a range of 8 to 20 gpm per square foot is used. For applications such as algae removal, bio-clarifier effluent polishing and river water treatment, flow rates between 2 and 8 gpm per square foot are used.

Flow Control— Each filtration application is analyzed to determine which of the following flow control methods is best suited:

- Influent Flow Splitting
- Effluent Rate-of-Flow Control
- Variable Flow Declining Rate

Dravo has experience in all of the above methods as well as other control variations.

Underdrain Design— A unique design feature is the nozzleless filter bottom, which is made of domed-shaped, high-strength concrete air/water distribution blocks. These blocks are hollow with open bottoms and are arranged in rows on the level floor of the filter compartment. The correct spacing of the rows is assured by lugs cast on the sides of each block. (See illustration.)

The bottoms of the air/water distribution blocks are arched to permit free passage of the filtrate through open slots in the floor to the filtrate channel. The openings are carefully designed to maintain low water velocity and pressure drop. The head loss through the air/water distribution system is measured in inches rather than pounds due to this unique nozzleless design.

Backwash— The effectiveness of the deep-bed filtration concept is dependent upon complete removal of retained material at every backwashing. Therefore, the success or failure of any filter system is dependent upon the efficiency of the backwash technique employed.

Effective Air/Water Scrubbing— The Dravo Deep-Bed Filter uses an air and water backwash with a water rinse. The backwash air is introduced via a distribution system installed under the rows of air/water distribution blocks. The blocks are equipped with large ports formed into the sides at the highest point. As the air passes upward through the supporting layers of graded gravel, it is dispersed uniformly over the entire filter bottom in a pattern of coarse bubbles. Backwash water is usually supplied from the same system used for filtrate collection. Nozzles are not used. Consequently, the major maintenance problem of plugged nozzles and media removal usually associated with nozzles is eliminated.

The air and water are introduced simultaneously. This allows the air bubbles to provide the needed scouring action and an airlift pump effect to carry the loosened solids to the surface for removal. Chemical cleaning is not required to remove the oily films retained during filtering.

BACKWASH RATES Total backwash water required is the same for the 3- and 4-component Mixed Media beds (100 gallons per square foot), but backwash rates can vary. A comparison of backwash requirements is shown below (in gpm per square foot):

Temperature	(4-component) MF 196	(3-component) MF 196
90° F.	22 gpm/ft²	21 gpm/ft²
70° F.	19 gpm/ft²	17 gpm/ft²
60° F.	18 gpm/ft²	15 gpm/ft²

INITIAL HEADLOSS Typical starting headlosses for a Mixed Media filter are 1.25 to 1.5 feet at a five gpm per square foot filter flow rate.

ACTUAL APPLICATIONS Microfloc filtration technology is at work today in a wide range of applications—from small 10 gallon per minute self-contained water treatment plants to large industrial and municipal water and waste treatment installations. Some examples:

COAL RIVER, W. VA.—0.8 MGD Microfloc Modular Aquarius plant provides municipal water treatment.

PHARR YARNS, McADENVILLE, N. C.—Three 8-foot skid mounted vertical pressure filters provide tertiary filtration for a 0.7 MGD flow of textile dye waste.

HATFIELD TOWNSHIP, PA.—Tertiary treatment system, including Microfloc Mixed Media pressure filters, reclaims 3.6 MGD of municipal waste water.

CLACKAMAS WATER DISTRICT, OREGON—20 MGD water treatment plant uses four 20 x 22 foot Microfloc Mixed Media gravity filters and polishes unsettled water to consistently less than 0.2 JTU.

GEORGIA-PACIFIC, SAMOA, CALIFORNIA—Industrial plant uses Mixed Media pressure filters to provide process water at the rate of 30 MGD.

WINNETKA, ILLINOIS—11 MGD municipal plant expanded capacity by converting to Mixed Media beds in existing filters.

Current Microfloc Mixed Media filtration is extensive. Total installed capacity, including industrial and municipal systems for both water and waste treatment, exceeds 2.5 billion gallons per day.

Litho in U.S.A.

FILTER EVOLUTION Mixed Media filtration has become widely accepted as the standard in high-rate, high-performance filtration technology. Mixed Media uses a combination of three or more materials to approach the coarse-to-fine grain configuration of the ideal filter. This significant development by Neptune Microfloc research makes possible safe, reliable filtration at advanced filter rates. The practical application of this technology arose from a continuing evolution in filter design.

Development of high-rate filtration began in the 1940's with work aimed at overcoming the disadvantages of rapid sand filter beds. Rapid sand filters were plagued by fast headloss buildup and a tendency to blind. Hydraulic grading during backwash would shift the finest sand grains to the top of the bed causing most of the filtration to be done in the top few inches of the bed and thus creating the headloss and blinding problems.

Preliminary research resulted in the 2-media filter—a layer of coal over a layer of sand. The layer of coal opened up the top of the bed, extending the effective filtration depth. This configuration offered more acceptable headloss characteristics, but presented other problems. Replacement of the finer sand with coarse coal reduced overall media surface area in the filter, lowering the filter's stability and filtering efficiency. The sand could not be graded finer to restore stability and efficiency because it would regrade above the coal upon backwash. As a result, the coal-sand filter proved to be susceptible to breakthrough when surged, and had difficulty producing satisfactory effluent and long filter runs under high solids loading conditions.

The 3-component Mixed Media filter developed in 1962 by Neptune Microfloc research under the direction of Walter R. Conley solved the problems of the coal-sand filter while retaining its improved headloss characteristics. The 3-component filter, through its unique inverse void graduation, provided for higher filtration rates, long filter runs and consistently higher effluent quality than had been possible before. Materials of differing size and specific gravity were intermixed coarse to fine in the filter bed, providing superior performance while maintaining a stable configuration even after long periods of use and backwash. Introduction of a very fine high-density media restored the stability and efficiency lost in the coal-sand filter by increasing the total media surface area in the bed.

Four-component Mixed Media is the latest Microfloc development. Formulated for the tougher filtration jobs—municipal secondary effluent, industrial wastes, or unsettled water—the 4-component filter adds a layer of special

Mixed Media filter materials shown are, from top: low density anthracite, regular anthracite, silica and garnet. These materials intermix in the filter bed, forming an inverse-void gradation.

BULLETIN No. [illegible]

Three and four-component Mixed Media filter beds closely approach the ideal configuration as shown on the media comparison chart above. Graph at right provides media particle distribution percentages showing typical Mixed Media filter bed composition.

light coal to the top of the filter bed, extending Mixed Media's traditional coarse-to-fine gradation. Storage capacity is increased so the filter can accept even higher influent solids loadings, provide longer filter runs, or operate at higher rates. Filter runs are 25 to 50 percent longer at the same solids loading or are the same length at a 25 to 50 percent higher solids loading.

THE IDEAL FILTER Theory states that in the ideal filter, media grain size should decrease uniformly in the direction of flow. This configuration provides an infinite series of progressively finer "screens" which remove increasingly smaller particles and distribute the captured solids throughout the entire depth of the bed. Slow headloss buildup, ability to accept higher solids loadings, and longer filter runs result; and consistent filtered water quality is maintained. The removal of fine suspended solids is assured by the fine final grains in the filter.

Maintaining coarse grains above finer ones and achieving the important intermixing needed to produce a nearly uniform decrease in grain size requires the use of materials of different sizes and specific gravities. Neptune Microfloc's 3-component Mixed Media was developed using materials ranging in size from 1.5 mm to 0.15 mm and in specific gravities from 1.6 to 4. These materials intermix, with particles distributed in the bed as shown in the graph at top right. 3-component Mixed Media filters can run at higher

filtration rates, obtain longer filter runs, handle solids loadings and produce higher quality effluent than either the rapid sand or coal-sand filters.

For some filtration jobs—municipal, secondary, effluent, industrial wastes, or unsettled water—theory suggests that addition of a coarser, fourth component to the top of the filter would provide additional improvement in headloss characteristics and filter run length, producing a filter more closely approaching the ideal configuration (see comparison graph above left).

This fourth component, a low specific gravity coal, makes it possible to change the top grain size of the filter from a mean of 1.4 mm to 2.4 mm without changing the grain size of the other three components. The larger grain size at the top of the filter significantly increases solids holding capacity. This increase can vary from 15 to 100 percent depending on the nature of the material being filtered.

IN THE FILTER BED Mixed Media has been effective in a wide range of filtration applications and readily adapts to most filtering equipment. The filter box schematic at middle left, opposite page, illustrates a gravity filter configuration typical of package and modular treatment systems and of larger municipal facilities. A pipe lateral underdrain system rests on the floor of the filter, collecting filtered water and introducing backwash water. Over this is placed a supportive layer of silica gravel and a second supportive layer of high-density gravel. The high-density gravel is used to prevent the fine high-density media from sifting down into the support gravel and to evenly distribute backwash water: Microfloc has support gravel configurations designed to cover most common underdrain systems. The Mixed Media filter bed is installed on top of the support gravel under the supervision of highly trained Neptune Microfloc technical directors. The media is carefully placed and hydraulically graded to insure the proper configuration for optimum performance. Above the Mixed Media surface are the surface wash arms and backwash troughs.

Vertical and horizontal pressure filters (horizontal shown at top left) also effectively utilize Mixed Media. Mixed Media and supportive gravel are installed in the same manner as in gravity filters, and the underdrain system operates similarly. Microfloc prefers pipe lateral underdrains with pressure filter systems.

Water depth in gravity filters ranges from 7 to 14 feet; and in pressure filters from 8 to 10 feet. Mixed Media beds for either filter type are normally 30 inches deep, variable to 36 inches when required; and support gravel layers range from 10 to 16 inches deep, depending on the underdrain system utilized.

WATER AND WASTE TREATMENT Mixed Media filtration technology is applicable to both water and waste treatment.

The Mixed Media filter design used in potable water treatment utilizes larger proportions of finer filtration materials to insure safe, reliable production of the highest quality filtered water. The large surface area of the finer materials provides the filtration capability needed for producing high clarity water and the stability against solids or hydraulic surges needed for safe operation. Coarser materials in the top of the bed assure adequate filter runs, but the key is the safety provided by the lower portion of the Mixed Media filter.

In advanced waste treatment, the criteria for efficient filtration are longer filter runs and satisfactory effluent quality. A coarser filter is required to satisfactorily remove the chemical and biological solids generated in secondary and tertiary treatment processes. The Mixed Media filter is opened up by increasing the proportion of coarser materials. A coarser, light anthracite is used to replace a portion of the regular coal, thus increasing storage capacity in the top of the filter. This reduces headloss, extending filter runs. Fine materials in the lower part of the Mixed Media bed polish the effluent to produce the tertiary quality desired. Satisfactory quality and operation efficiency are balanced.

Typical flow rates for Microfloc Mixed Media filters are 5 to 10 gpm per square foot for municipal water and waste treatment applications and 5 to 20 for industrial applications. These rates are variable depending on the nature of the filtration problem.

TAILORED FILTERS The versatility of Mixed Media makes it possible to vary filter bed configuration to meet specific client needs. Grain size, filter depth, and media quantities can be altered to meet the desired balance of filtered water quality and filter run length.

Microfloc starts with standard bed designs, then tailors these designs to fit individual applications. For the majority of municipal and industrial water supply applications, the MF 188 filter bed is recommended. This bed provides the balance of filter run length and filtered water quality most often required in water treatment. It is composed of 55 percent low density material, 30 percent medium density, and 15 percent high density.

MF 198, a 4-component Mixed Media bed, is generally recommended for most of the tougher filtration jobs. The extra capacity of this bed design makes it ideal for filtering industrial waste, municipal wastes, and unsettled or flashy raw water. The 4-component bed is also ideal for handling heavy algal loading and high solids surges.

The MF 188 and MF 198 bed designs can be varied to suit specific application requirements. Raw water or waste characteristics, required effluent quality, rate of filtration, and desired filter run length can all be balanced by custom designing the composition of the filter bed. The chart at the left illustrates the most common variations of 3- and 4-component Mixed Media. Variation of filter media materials also makes possible the control of starting headlosses and backwash rates.

Application and results of deep bed filtration

by JOHN A BUCHANAN, Pr. Eng, B.Sc, A.P.T.C, M.I. Chem.E, A.M.I.W.P.C.

Mr Buchanan, who is managing director of Prentec (Pty) Ltd, has had more than 25 years experience in constructing, research and development, and production. For the past 10 years he has worked exclusively on water and effluent treatment both as a consultant and contractor.

INTRODUCTION

Filtration of a liquid may be defined as the passage of the liquid through a porous medium whereby the matter held in suspension in the liquid is removed.

In the field of water and effluent treatment, the most common type of filtration equipment employed is the rapid gravity filter in which the porous filtering media is a fixed bed of carefully screened sand. The liquid flows vertically downwards. In the rapid gravity filter, in common with most types of downflow filters, the majority of the filtered-out suspended matter is collected in the upper part of filtering media and the full dirt holding capacity of the filter is not realised. Deep bed filters are a development to enable almost 100% utilisation of the filtering media dirt holding capacity, with progressive filtering from coarse to fine layers of media in some cases.

Deep bed filtration is better defined as in-depth filtration since it is the in-depth filtering process which is more important than the depth of the filter bed.

Several types of deep bed filters are available on the market, e.g. mixed media, anthracite/sand, biflow, contact, etc, but none has been as successful as the Immediumfilter which is an upflow sand filter developed and patented worldwide by Imacti, Holland (South Africa patent number 60/1283).

In this paper, the Immediumfilter is employed to illustrate the principle advantages and applications of deep bed filtration.

PRINCIPLE OF THE IMMEDIUMFILTER (Dual Filter)

Figure 1 illustrates a typical cross-section of the downflow gravity or pressure type filter and the upflow sand Immediumfilter. Structurally the filters are very similar; both have a retaining wall and filter bed support plate provided with nozzles, with the various grades of media placed on top of one another.

In the conventional downflow filter, the unfiltered liquid passes through the sand, gravel and stone layers in that order, and leaves the filter from the bottom. This results in the top part of the sand layer collecting the majority of the suspended matter with little penetration of the matter into the filtering media. The dirt penetration can be increased by applying high pressure/flow to the filtering media. However, this causes an increase in pumping costs, a lowering of the filtered water quality and possible declassification of the filtering media.

Figure 1. Typical section through a sand filter

FIGURE 1. TYPICAL SECTION THROUGH A SAND FILTER

Common sense suggests that the filter should be fed from the bottom, thus allowing the flow to pass through the media layers progressively from the coarse stone to the fine sand. If the upflow principle is applied to the conventional sand filter, the filter run would be very short and the filtrate quality poor due to spasmodic breakthrough of the filter bed. To completely eliminate this breakthrough, the Immediumfilter is provided with a grid as shown in *Figure 2*. During filtration, a natural arching arrangement is formed between the sand grains and the grid bars, thus ensuring that the filtering media is held rigidly in position. The unfiltered liquid enters from the bottom and passes through the stone, gravel, coarse sand and fine sand layers, in that order, and leaves the filter from the top. The lower part of the filter containing the coarser media thus acts as a prefilter, the upper part as a polisher, and the intermediate section, because it contains coarse sand grains, provides the dirt holding capacity for the suspended matter being removed.

Cleaning of the Immediumfilter is achieved by first air scouring the media with low pressure air and then fluidising the media through the grid, thus releasing the collected dirt in the normal way to the backwash collecting launder or pipe.

ADVANTAGES OF THE IMMEDIUMFILTER (Dual Filter)

The upflow sand Immediumfilter has, in thousands of installations, clearly demonstrated the many advantages over the more conventional downflow sand gravity or pressure filter. *(Table 1)*.

APPLICATIONS OF THE IMMEDIUMFILTER (Dual Filter)

The Immediumfilter has been successfully applied in all filtration processes where the fixed filter media bed technique is employed. Some of the more common applications are shown in *Table 2*.

The performance and advantages of the Immediumfilter have been well proven in practice and, in order to illustrate its flexibility and reliability, two installations are described which vary greatly in capacity and duty. The Immediumfilter can be con-

Table 1

Advantages	Effects
Larger dirt holding capacity	longer service cycle. higher water efficiency. reduced labour requirements.
Higher service velocity	less filtration area required. large saving in capital cost. less overall plant area required.
Filter cleaned with feed water	no separate washwater storage required. large saving in capital cost. greater flexibility in plant design.
Simpler to operate	reduced labour cost. reduced maintenance cost.
Lower headloss experience	reduced operating power cost. more positive control.
No blinding or mudballing of media experienced	reduced labour and maintenance costs. greater plant efficiency.
Ideal for in-line flocculation or contact filtration.	large saving in capital cost. immediate and positive treatment. simplifies plant operation.

structed in concrete when the design filtering area becomes too great to make it viable to fabricate the plant in steel.

POTABLE WATER PLANT

At the Drakensberg Pumped Storage Scheme near Bergville, Natal, the Electricity Supply Commission produced up to 90 m³/h of potable water by treating raw water from the pump station forebay.

The treatment plant consists of 5 pyramidal bottomed settling tanks followed by 3 Immediumfilters (*Figure 3*). The water is chemicated with aluminium sulphate and soda ash solutions, mixed by means of an in-line mixer and the bulk of the floc produced settled out in the settling tanks. Because of the relatively high upflow velocity of 2,0 m/h in the settling tanks, the carry-over of floc to the filtration section varies between 5-20 ppm. This solids loading would prove excessive for conventional downflow filters, but the Immediumfilter readily handles the load.

If required, the plant can be operated with the settling tanks bypassed. This involves rendering the raw water potable by employing the technique of in-

Figure 3

line flocculation into the immediumfilter

Turbidities of over 200 ppm have been successfully removed in the plant, and a consistently very high clarity of water produced. Therefore, when the raw water has a turbidity of less than 200 ppm, this technique can almost halve the capital cost of a water treatment plant.

Figure 4

In both applications, dirt holding capacities of 3 kg/m³ were obtained by the Immediumfilter, which is approximately 10 times greater than that expected by a rapid gravity sand filter.

EFFLUENT TREATMENT PLANT

At ISCOR's Vanderbijlpark Works, the effluent arising from the steel works is handled by the terminal effluent treatment plant. The basic steps of treatment are:

- descalping in scale pits;
- oil skimming;
- settling in horizontal flow settlers;
- low lift pumping;
- filtration by Immediumfilter.

The total capacity of the plant is 5 500 m^3/h and the prime objective of the filters is to render the effluent acceptable for recycling to the works, and/or for discharging into the River Vaal, by removing the suspended matter and oil to the desired levels.

The filtration section of the plant (*Figure 4*) consists of a block of 18 Immediumfilters constructed in concrete. The feed to each filter is kept constant irrespective of the solids loading in the filter, by means of equilibrium control chimneys. A summary of the operating results are shown in *Table 3*. Dirt holding capacities well in excess of 7 kg/m^3 have been achieved but, in order to maintain a high degree of filter cleanliness, the operating dirt holding capacity employed is 5 kg/m^3.

The removal of oil from effluents by means of sand filtration is considered by many to be non-viable. However, the above results clearly show that the sand Immediumfilter, with its in-depth filtration action, performs well in this difficult operation.

Table 3

	Influent		Filtered	Removal
	Average	Peak	Water	efficiency
Total suspended solids (ppm)	40	1 000	2	95-99%
Total oil content (ppm)	10	50	1	90-98%

CONCLUSION

Immediumfilter installations have clearly proved that deep bed filtration is an important tool in the field of filtration and it is the author's opinion that this tool is not exploited fully in South Africa.

CROSS-FLOW FILTRATION/ULTRAFILTRATION

For suspended solids removal from water, the new technologies employing cross-flow filtration and ultrafiltration (incorporating cross-flow filtration principles) are believed to offer significant advantages. These systems will no doubt play greatly increased roles in the years to come in the removal of suspended solids from water.

The principle on which this technology is based is to use a dynamic membrane built up from the material that is being filtered from a recirculating slurry of the solids fraction which is mixed back into the feedwater. There are three main untrafiltration/cross-flow filtration system vendors.

Romicon, Inc. supplies potential users with an excellent booklet entitled, "Ultrafiltration Handbook," which explains the principles of cross-flow filtration and ultrafiltration and its applications. Another description of the process by COMSTOCK, et al. (1983) describing the cross-flow microfiltration process is inserted below. Remarkable solution fluxes are achieved with even small cross-flow filtration units.

One other version of cross-flow filtration and its application in minewater treatment was demonstrated at the ARGO Tunnel and described by HOLM and SIMPSON (1981). A copy

of their paper is inserted in Chapter 24 on acid mine drainage treatment. The Wannamaker continuous concentrator is said to function best in removing crystalline particles 1-10 microns in size. The portable test unit treated about 80 gpm of feedwater.

The simple cross-flow filtration system employed used a porous fabric media which looked similar to a porous firehose. The precipitate was recirculated and allowed to build up until there was enough of it that a bleed became necessary. The experiment was conducted by:

Excerpt from:

Removal of Trace Elements and Acidity from the ARGO Mine Tunnel Drainage. J. DAVID HOLM and DONALD H. SIMPSON, April, 1981.

A precipitate concentration and filtration device was tested at the Argo Mine Tunnel. The system used was a Wannamaker Continuous Concentrator furnished by Colorado Minerals & Chemicals Ltd. with a capacity of 57,600 gpd product flow.

This particular continuous concentrator apparatus is a relatively simple device designed to fractionally remove solids from liquid-solid suspensions or slurrys. The continuous concentrator is essentially portable and employs a modular design so that a wide range of flows can be treated. The system uses relatively little floor space and was installed inside a building near the portal of the Argo Mine Tunnel.

The device was used simply to remove minerals from mine water using a precipitation and filtration process. A schematic of the continuous concentrator apparatus is presented in Figure 1.

Continuous Concentrator System Evaluation

Sampling of the effluent from the continuous concentrator water treatment/minerals recovery system at the Argo Tunnel was performed on October 15, 1980. The test unit was operated as a single stage multipass concentrator with an intermittent feed of raw mine water and a continuous product flow of clear effluent water. The concentrated sludge was discharged from the tank following the experiment. The sludge has not yet been assayed for mineral content.

Samples of processed water or effluent were taken as the system was operated at various pH values. The objective of the sampling program was to determine the optimum pH range which provided maximum precipitation of dissolved metals in the Argo Mine drainage and produced an effluent of acceptable quality. Approximately 450 gallons of raw water draining from the Argo Mine Tunnel was pumped into the concentration consolidation tank and sampled for pH and baseline metal concentrations. Industrial Grade Caustic Soda (NaOH) was then added to the tank in measured increments until the pH of the mine water was raised to 11.5. The mine water and sodium hydroxide were thoroughly mixed using the centrifugal pump and a return line to the consolidation tank. After complete mixing this water was then pumped into the continuous concentrator and the system was operated for 5 minutes and allowed to reach equilibrium. An effluent sample was obtained and analyzed for pH and metal concentrations.

The system was operated continuously and effluent samples were obtained at pH 11.5, 10.5, 9.8, 8.3, 7.2, 6.6, 6.0 and 5.6. The pH was lowered gradually by simply adding raw mine water to the consolidation tank (which had originally been spiked with NaOH). At each desired pH level the system was allowed to equilibrate prior to extracting effluent samples. The pH of all effluent samples was measured immediately with a pH meter. All samples were acidified with HNO_3 and analyzed on an atomic absorption spectrophotometer by the Industrial Laboratories Company. The following parameters were analyzed: Total dissolved solids, sulfate, sodium, arsenic, cadmium, chromium^{+3}, chromium^{+6}, copper, iron, manganese, lead and zinc. The results of the examination of the effect of increasing pH on removal of trace elements from the Argo Mine drainage using the continuous concentrator system are presented below.

HYDROPERM™ CROSS FLOW MICROFILTRATION
A NEW PROCESS FOR THE LIQUID PROCESS INDUSTRY

BY
DANIEL L. COMSTOCK
ANDREW K. HSIUNG
JOSEPH A. MILLEN
OF
NEPTUNE MICROFLOC, INCORPORATED

Introduction

Cross flow microfiltration is a new solids/liquid separation process that has grown out of microfiltration technology.

The objective of this paper is to highlight the factors that govern the theory and practice of this intriguing new process and to present lime softening and seawater reverse osmosis pretreatment pilot study data. Lastly, the benefits of HYDROPERM™ Cross Flow Microfiltration will be presented for these applications.

Through Flow Vs. Cross Flow Microfiltration

Commercial through flow microfilters consist of flat sheets or discs and cartridge filters which are commonly used for laboratory and industrial separations. In both cases, feedwater is introduced at right angles to the membrane surface.

Cross flow microfiltration is a generic description of a category of processes that combine microfilters and tangential feedwater flow. Figure 1 illustrates through flow and cross flow microfiltration concepts.

Included in the cross flow microfiltration category are ultrafilters and reverse osmosis unit processes. In both reverse osmosis and ultrafilter processes, a thin solids rejecting membrane is deposited over a microporous support structure.

One subcategory of cross flow microfiltration includes microfilter elements that do not have a fixed rejecting membrane and do not reject dissolved (ionic) solids or macromolecules. HYDROPERM™ Cross Flow Microfiltration falls into this category. Instead of requiring a fixed, solids rejecting membrane, a dynamic membrane is formed on the inner surface of the filter element by the material being filtered. Figure 2 is an electron photomicrograph of a single HYDROPERM™ filter element. Each filtration tube has an inside diameter of 6 mm and contains pores that average 2 microns in diameter. The pores comprise 65 percent of the tube wall volume. HYDROPERM™ modules are made up of many such tubes. Module construction is illustrated in Figure 3.

The HYDROPERM™ Cross Flow Microfiltration Process

To best describe the HYDROPERM™ Cross Flow Microfiltration process, it is instructive to compare and contrast it to a tubular ultrafilter device. Typically, ultrafilters operate on feedwater that contains relatively low levels of suspended solids. Feedwater flows through the lumen of the tubular elements with the filtrate permeating outward through the walls. A typical feedwater suspended solids concentration is about 15 mg/L. The reject suspended solids concentration might be on the order of 150 mg/L. Pretreatment chemicals are not employed, and feedwater velocity through the ultrafilter elements is typically in the laminar to low turbulent range depending upon the application and type of ultrafilter.

Ultrafilters depend upon a thin, fixed, surface membrane for particulate rejection. Pore sizes may be engineered to reject macromolecules as well as larger particulate material. System pressures generally fall into the 25-35 psig range. At this pressure, distilled water fluxes are on the order of 150 gpd/sq.ft. of membrane area. Distilled water flux to module volume ratio is about 45,000 gpd/cu.ft. Operating flux rates are generally in the 25 gpd/sq.ft. range, giving a flux to module volume ratio of 7,500 gpd/cu.ft.

HYDROPERM™ filtration tubes do not use a fixed rejecting membrane but rather a dynamic membrane formed from the material that is being filtered, Figure 4. It is this membrane that actually rejects particulates. Feedwater velocity within the filter elements is within the turbulent regime (Reynolds number of 18,000). System pressures are similar to ultrafiltration and fall into the range of 25-35 psig. Distilled water flux is on the order of 3,000 gpd/sq.ft., giving a flux/module volume ratio of over 200,000 gpd/cu.ft. Operating flux rates in the 1,000 gpd/sq.ft. range are typical, resulting in a flux/volume ratio of 66,000 gpd/cu.ft.

HYDROPERM™ Cross Flow Microfiltration may also operate on feedwater containing very high levels of suspended solids. For example, flux rates of 1,000 gpd/sq.ft. have been achieved at suspended solids levels as high as 5-8 weight percent through the HYDROPERM™ tubes.

Pretreatment chemicals are often employed to improve the rheology of the filtered solids. Table 1 compares the physical and process capabilities of the two unit processes.

In terms of solids loading, HYDROPERM™ Cross Flow Microfiltration overlaps and even surpasses the capabilities of clarifiers and thickeners. Clarifiers can generally operate to a solids loading limit of 20-40 lbs/day/ sq.ft. of clarification area. Granular media filters can tolerate about 0.2 lb. solids/day/sq.ft. A typical HYDROPERM™ module solids loading rate is 150 lbs/ day/sq.ft. of tube area.

Figure 5 illustrates how cross flow microfiltration relates to other unit processes with respect to filtrate quality. Reverse osmosis rejects dissolved (ionic) solids as well as macromolecules and colloids. Ultrafilters overlap reverse osmosis with respect to rejection of macromolecules and colloids. HYDROPERM™ Cross Flow Microfiltration has demonstrated particle size removal down to 0.5 micron.

HYDROPERM™ Cross Flow Microfiltration System Operation

At this time, three specific commercial applications for cross flow microfiltration have been studied. These include metal plating waste treatment and recovery, lime softening of municipal and industrial waters, and seawater reverse osmosis pretreatment.

A description of the HYDROPERM™ lime softener will best serve to illustrate the system concepts. Raw water to be treated enters the system through a small reaction tank with approximately 4 minutes of detention time. The reaction tank is only required when a chemical reaction must take place ahead

of the HYDROPERM™ Cross Flow Microfiltration unit. Lime and sometimes a rheology aid (metal salt or polymer) are added directly to the reaction tank. Solids concentration is maintained at about 2 weight percent within the tank to accelerate the softening reactions and to retard scale formation. The slurry is pumped into the filtration loop by a makeup pump which maintains pressure within the loop at about 35 psig, and a second recycle pump moves slurry through the HYDROPERM™ tubes at a constant velocity. Filtration takes place through the porous tubes in a direction perpendicular to the slurry flow. Product water is collected from around the outside of the tubes and flows to storage. A portion of the concentrated slurry (5-7 weight percent) is recycled back to the reaction tank as a moving sludge blanket. A small portion of the thickened sludge is also wasted from the filtration loop as blowdown. Generally, the blowdown flowrate represents about 0.5 percent of the raw water makeup flowrate.

After a period ranging from 12 hours to several days, the filtration run must be terminated due to high differential pressure across the HYDROPERM™ module. The system is then flushed with raw water, and a cleaning solution is recycled through the filtration loop for about 5 minutes. Following a second brief raw water flush, the unit is brought back on-line in the filtration mode. All cycles are initiated automatically. Figure 6 illustrates these operational modes. Figure 7 is a system drawing.

The reverse osmosis pretreatment system is very similar to the lime softener except that a reaction tank is not needed and sludge recycle is not required.

Nonequilibrium Operation

State of the art cross flow microfilters such as reverse osmosis and ultrafilters operate in an equilibrium filtration mode. That is, differential pressure across the microfilter remains constant while the flux or filtration rate is allowed to decline to a lower equilibrium value, Figure 8. During the initial declining or nonequilibrium phase, the dynamic membrane is deposited. Also during this phase, flux rate is directly proportional to recycle velocity and differential pressure, and flux is inversely proportional to slurry concentration and time as indicated by the following formula:[1]

$$F = K\, V^{a}\, \Delta P^{b}\, C^{-c}\, t^{-d}$$

Where, F = flux rate
V = recycle velocity
ΔP = differential pressure
C = slurry concentration
t = time
a,b,c and d are filtration exponents

When the dynamic membrane is fully formed, flux rate reaches a plateau. At this stage, differential pressure drops out of the equation and flux rate

[1]Marshall Tulin, NSF Proposal, 1980.

is only a function of velocity, slurry concentration, time, and the filtration constant.

By contrast, HYDROPERM™ Cross Flow Microfiltration is operated in the nonequilibrium phase which is characterized by higher flux rates created by partially throttling the product valve and providing an intermittent product water backflush through the tube walls. Flux rate can therefore be held constant while differential pressure is allowed to increase as illustrated by Figure 9.

By rearranging the equation for nonequilibrium operation, one obtains:

$$\Delta P = \frac{K F^{\frac{1}{b}} C^{\frac{c}{b}} t^{\frac{d}{b}}}{V^{\frac{a}{b}}}$$

This equation best describes the nonequilibrium, constant flux mode of HYDROPERM™ Cross Flow Microfiltration operation.

Differential pressure increases as the flux rate, solids concentration and time increase. Differential pressure decreases with increased recycle velocity. Improvements in solids rheology have the effect of decreasing the exponents of flux, solids concentration, and time. The exponent for velocity is increased and the filtration constant (K) is decreased.

Rheology Considerations

Control of the dynamic membrane is a key to successful cross flow microfilter operation. By proper chemical pretreatment, the erosion characteristics of the dynamic membrane can be improved markedly. This allows operation of the cross flow filter at significantly higher flux rates for longer periods of time. As an example, Figure 10 plots the development of differential pressure with time for two lime softening runs. The upper curve is from a run that employed lime only. The lower curve was obtained from a run that was made with lime and a small quantity of an organic polymer. The flux rate was 1,000 gpd/sq.ft. in each case.

Lime Softening Applications

A number of lime softening pilot studies have been conducted. Data from the pilot study at Nanton, Alberta, Canada, is presented below.

The water source for the town of Nanton is a meandering prairie stream that is high in hardness and also contains silt, clay, algae, and some iron. Table 2 tabulates raw and HYDROPERM™ Cross Flow Microfilter softened water quality parameters. Figure 11 plots differential pressure and blowdown suspended solids concentration as a function of time. Excellent quality softened and filtered water was produced, and HYDROPERM™ Cross Flow Microfilter run times were in excess of several days. A constant flux rate of 1,000 gpd/sq.ft. was maintained. Product water recovery in excess of 99% was achieved. Weight percent suspended solids in the blowdown averaged 5 percent.

An on-going lime softening study is being conducted in Corvallis, Oregon, on hard well water. This water is low in turbidity but contains moderately high levels of carbonate hardness.

Figure 12 plots softened water quality parameters. Run times average 12 hours or more at a flux rate of 1,000 gpd/sq.ft. of tube area. Product water recovery is greater than 99 percent.

Seawater Filtration

Table 3 tabulates seawater pretreatment data from a pilot study run at the Oregon Coast. Ferric sulfate was added to the raw seawater as a rheology aid at a dosage of 20 mg/L. Filter run times were equal to or greater than 12 hours at a flux rate of 1,000 gpd/sq.ft. of tube area. Silt Density Indexes[2] were always below 1.5 percent/minute regardless of the changing quality of the raw seawater. While not a reliable predictor of reverse osmosis feedwater quality, filtered water turbidities were always less than 0.2 NTU.

Advantages of HYDROPERM™ Cross Flow Softening

Conventional lime softeners have been used successfully for over 40 years. Any new process or technology must offer some attractive alternatives in order to warrant consideration as a replacement. HYDROPERM™ Cross Flow Lime Softening does this. The advantages begin with low installed cost and continue with features such as compact equipment size, simplified operation and improved product quality. The major benefits are numerous:

Low installed cost. HYDROPERM™ softeners provide a significant installed cost advantage over conventional softeners. Installed cost is comprised of three major factors: process equipment, floor space, and installation. HYDROPERM™ Cross Flow softeners provide a savings in all three categories. The compact HYDROPERM™ Microfilter systems have a lower process equipment cost, and installation of a skid-mounted process provides savings in labor.

The installed cost savings offered by HYDROPERM™ softeners has been shown to range from 30 to 50 percent over a wide range of flows.

Ease of operation. Unlike conventional softener-filters, cross flow softeners may be turned off and on without a lengthy restabilization period. In addition, filter breakthroughs cannot occur and there are no sludge blanket control problems. This feature is especially important when softened water is needed only intermittently or when water demand is tied to process needs, shift operations or peaking cycles.

[2] Silt Density Index is the standard test used to characterize reverse osmosis feedwater quality. The test is performed by forcing filtered water through a 0.45 micron pore size Millipore microfilter. The decay in flowrate at the end of 15 minutes of flowing is an index of the quantity and quality of colloidal material present in the raw water.

Recarbonation not specifically required. Recarbonation is not specifically required for operation of the HYDROPERM™ Cross Flow softener. Recarbonation can be included if stabilized water at a lower pH is desired in the distribution system. Conventional systems require recarbonation prior to filtration to prevent incrustation of the media or underdrain.

Convenient sizes. Modular construction using one, two or three module systems is available that gives a broad range of flow rate options. System capacity can also be increased at a later date by simply adding another skid.

Superior effluent quality. Water quality in terms of particulate removal rivals that of ultrafilters. Virtually complete bacterial removal has been demonstrated, and extremely low silt density index values are always achieved.

Power consumed by the HYDROPERM™ softener average 1 kw-hr/1,000 gal. of softened water produced. Chemical consumption is the same as for conventional softeners.

Advantages of Reverse Osmosis Pretreatment by HYDROPERM™ Cross Flow Microfilters

Granular media filters have traditionally been used for reverse osmosis pretreatment. The major disadvantage of granular media filters for seawater pretreatment is that they cannot reliably and consistently produce low SDI feedwater. Cyclical changes in the raw water quality and the complex nature of seawater can make the process chemistry required for good granular media filter operation too complex for plant operators to handle. HYDROPERM™ Cross Flow Microfilters always produce a superior product water regardless of the raw water quality. In addition, filtered water quality is independent of the rheology aid added to the HYDROPERM™ Cross Flow Microfilter system.

The cost of a HYDROPERM™ system parallels that of a good automatically controlled granular media pressure filter system. HYDROPERM™ Cross Flow filters are also skid mounted for easy installation and they occupy a minimum of floor space.

Power consumption for the RO pretreatment units is 0.8 kw-hr/1,000 gallons of filtered water. Chemical consumption is equal to or less than for granular media filters.

Conclusions

HYDROPERM™ Cross Flow microfilters make use of a dynamically formed membrane for solids rejection. The dynamic membrane may be controlled by chemical addition and by controlling the operational variables such as recycle velocity, flux rate, differential pressure and solids concentration.

HYDROPERM™ Cross Flow Microfilters offer significant technical and economic benefits for a variety of water, wastewater, and process stream treatment applications. Commercialized applications for metal finishing waste treatment, lime softening, and seawater reverse osmosis pretreatment have been

demonstrated. In the years to come, it is expected that cross flow microfiltration will be used for hundreds of applications that range from process stream solids/liquid separations to secondary wastewater pretreatment for reverse osmosis.

HYDRO

CROSS FLOW MICROFILTRATION

TECHNOLOGY

HYDROPERM™ cross flow microfiltration is a new solids liquid separation technology which substitutes a single process unit for clarification, filtration and thickening.

HYDROPERM™ combines the high flux rates of granular media filters with the thin-skin surface filtration aspects of membrane ultrafilters. Micron sized particles and colloids can be easily removed.

CROSS FLOW MICROFILTRATION (CFM)

Filtration processes can be divided into two general categories: **cross flow** and **through-flow.** In through-flow filtration, the flow of both influent and product water is perpendicular to the surface of the filter media; thus filtered particles continuously accumulate on and within the filter. As a result, filtrate flux steadily decreases with time due to particle build up. Periodic backwashing is necessary to remove accumulated solids from the filter.

In cross flow filtration, the direction of the feed flow is parallel to the filter surface, and filtration occurs through the porous tube wall in a direction perpendicular to the flow. Steady-state operation exists because the continuous buildup of solids on the filter surface is prevented by the hydrodynamic shear exerted by the cross flow.

- Steady state operation.
- Product flow direction is perpendicular to that of the feed flow.
- Particle build up is prevented by the shear induced by the feed flow.

ADVANTAGES

HYDROPERM™ systems have many advantages over conventional systems:

- **Low Cost.** HYDROPERM™ combines low capital and operating cost to provide a true, cost-effective process.
- **Ease of Operation.** HYDROPERM™ is simple; does not involve complex controls and requires no in-depth process knowledge.
- **Continuous Product Water Quality.** Regardless of raw water characteristics, chemical requirements or operator control, there will be no solids breakthrough.
- **High Filtrate Quality.** Product water quality rivals that of ultrafiltration at greater than 20 times the flux rate of ultrafiltration.
- **Reduced Chemical Usage.** Treatment chemicals are continuously recycled, resulting in substantially lower treatment costs.
- **Reduced Sludge Volume.** Solids thickening capabilities have been demonstrated up to 25 percent by weight.

HYDROPERM™ MODULES

HYDROPERM™ by Neptune Microfloc, Inc., utilizes thick walled, microporous plastic tubes. Pore structure is carefully controlled during manufacturing to obtain the performance desired. HYDROPERM™ tubes are:

- RUGGED
- INERT TO CHEMICAL ATTACK
- INERT TO BIOLOGICAL ATTACK
- NOT SUSCEPTIBLE TO THE HANDLING, FOULING AND CLEANING PROBLEMS OF MEMBRANE SYSTEMS.

HYDROPERM™ modules are assembled from microporous, plastic tubes. Individual tubes are bundled into modules and assembled into process units. HYDROPERM™ modules are available in various diameters and lengths for a wide range of process applications.

HYDROPERM™ SYSTEMS

The operation of a HYDROPERM™ system is shown below. Raw feed enters the HYDROPERM™ system at the recycle tank. Flow is continuously pumped from the recycle tank through the inside of the HYDROPERM™ tubes at relatively low pressure, typically 15 to 30 psi. Product water passes through the HYDROPERM™ tubes and is withdrawn through ports on the sides of the modules. The concentrated stream leaving the end of the modules returns to the recycle tank to be again concentrated by flowing through the module. Periodic or continuous blowdown of sludge from the recycle tank controls sludge concentration.

HYDROPERM™ EXPERIENCE

Extensive tests have been conducted on a variety of water and waste streams. Application has been demonstrated for both domestic and industrial streams including: acid battery wastes, metal finishing wastes, laundry wastewater, sewage, explosives wastewaters, seawater, estuary waters, turbid waters, and many other streams.

Reliable performance has been achieved at product fluxes of greater than 400 gallon/ft²/day at full scale commercial installations. Sludge dewatering capabilities have been demonstrated up to 25 percent by weight. Operating results at two installations are shown above.

HYDROPERM™ technology provides a new, more efficient means of simultaneously solving many clarification, filtration, liquid/solids separation and solids concentration problems. HYDROPERM™ cross flow microfiltration systems are perhaps the most cost-effective treatment alternative available today for jobs involving:

- FILTRATION OF TURBIDITY AND OTHER COAGULABLE SUSPENSIONS FROM POTABLE AND INDUSTRIAL PROCESS WATER.
- FILTRATION AND CONCENTRATION OF MANY SUBMICRON PARTICLES INCLUDING SILICA AND OTHER COLLOIDAL SUSPENSIONS.
- REMOVAL OF SUSPENDED SOLIDS FROM BOTH DOMESTIC AND INDUSTRIAL WASTE STREAMS.
- REMOVAL OR RECOVERY OF METAL HYDROXIDES FROM METAL PLATING WASTES.
- PRETREATMENT FOR REVERSE OSMOSIS AND DEMINERALIZATION.
- SOLIDS-LIQUID SEPARATION IN MANUFACTURING PROCESSES.

HYDROPERM™ CROSS FLOW MICROFILTRATION

CASE HISTORY NO. 72

CRAFTSMAN PLATING AND TINNING CORPORATION CHICAGO, ILLINOIS

ELECTROPLATING WASTE TREATMENT

Under EPA Grant No. R-807503-01-0, Design, Construction and Field Testing of a full scale HYDROPERM™ cross flow microfiltration system was conducted at an electroplating shop. The product from the demonstration unit was required to meet the standards set forth by the Metropolitan Sanitary District of Greater Chicago.

The HYDROPERM™ system was installed at the Craftsman Plating and Tinning Corporation in Chicago. CP&T's metal plating lines include cadmium, copper, tin, tin-lead, and zinc. Special treatment in the shop includes chromate conversion coating, etching, passivating pickling, hot solder dipping, and organic coating. All wastewaters flow to a common sump at 2,000 gallon/hour. From this point, CP&T was treating the wastewater by conventional processes using cyanide destruction, neutralization, suspended solids removal by clarification and centrifugal sludge thickening. The HYDROPERM™ system was placed in parallel with the existing clarifier for comparative performance tests.

A HYDROPERM™ system with 100 square feet of tube area was installed. Average flux values experienced in this demonstration were approximately 200 gallons per day per square foot (gf^2d) of HYDROPERM™ module area, with values as high as 600 gf^2d HYDROPERM™ module surface area being achieved. Talbe I presents the average results obtained at this full scale installation.

	TSS	Cd	Cu	Zn
Feed (mg/L)	6547	982	581	117
HYDROPERM Product (mg/L)	6	0.87	0.71	0.1
Sludge (mg/L)	approx. 12,000			

TABLE I

The CP&T field demonstration unit showed that HYDROPERM™ is an effective technology for removal of suspended solids in electroplating wastewater. Proper pretreatment is required to convert soluble constituents to suspended solids. In comparing the performance of the HYDROPERM™ system to a conventional system, the HYDROPERM™ system provides greater consistency in effluent quality with less operator attention.

HYDROPERM™ CROSS FLOW MICROFILTRATION CASE HISTORY NO. 70

GENERAL BATTERY CORPORATION
HAMBURG, PENNSYLVANIA

LEAD-ACID BATTERY WASTE

General Battery Corporation has over two years of operating experience using HYDROPERM™ technology to treat neutralized wastewater from a lead-acid battery manufacturing plant. The wastewater is generated from the manufacture of industrial and automobile batteries, and after neutralization has the characteristics shown in the table below. High suspended solids and lead concentrations are the major concerns at this plant, but significant levels of copper, zinc, nickel, arsenic and antimony must also be reduced to meet State and EPA standards.

The Hamburg plant is located where stream discharge is convenient and acceptable providing all Pennsylvania NPDES permit requirements are met. In all cases, the final filtrate produced by the HYDROPERM™ cross flow microfiltration system has substantially surpassed even the strictest limits, as indicated in the table of Treatment Results.

- Steady state operation.
- Product flow direction is perpendicular to that of the feed flow.
- Particle build up is prevented by the shear induced by the feed flow.

HYDROPERM™ Treatment Results

	Effluent From Neutralization Tank	HYDROPERM™ Filtrate To Receiving Stream	Percent Removal	Pennsylvania NPDES Permit Requirements Daily Average
pH	9.8	8-9	NA	6-9
SS	24,600 mg/L	0.6 mg/L	99+%	20 mg/L
Pb	54.2 mg/L	0.04 mg/L	99+%	0.14 mg/L
Cu	0.33 mg/L	0.015 mg/L	95.5%	0.04 mg/L
Ni	0.40 mg/L	0.032 mg/L	92%	0.07 mg/L
Zn	0.88 mg/L	0.007 mg/L	99+%	0.03 mg/L
As	0.17 mg/L	0.002 mg/L	99+%	0.01 mg/L
Sb	1.35 mg/L	0.292 mg/L	78.4%	0.97 mg/L

neptune microflox

At General Battery the treatment system includes a neutralization reaction tank for lime addition to raise the pH to a range of 8-9, a recirculation tank which acts as a sludge thickener and feed tank for the HYDROPERM™ system, two independent HYDROPERM™ treatment systems each containing 180 square feet of HYDROPERM™ tubes, a permeate holding tank and a cleaning tank. The HYDROPERM™ systems are skid-mounted and include feed pumps, valves and associated instrumentation for immediate field startup.

Flux rates of over 400 gallons per day per square foot of tube area are easily attained in the HYDROPERM™ unit. Normally only one system is on-line at any point in time to treat the wastewater at the plant. Operation is straight forward and plant maintenance personnel are used to run the facility. Solids content of the sludge withdrawn from the system has been in excess of 25% by weight. Module cleaning is practiced using a dilute HCl solution of approximately 2 percent. The filtrate is discharged directly to a small receiving stream.

REVERSE OSMOSIS (SEEDED SLURRY R.O.)

Reverse osmosis is not the category of process that would normally be considered as a candidate for suspended solids removal. Indeed, most forms of revese osmosis require some form of pretreatment of feed to deep suspended solids out of the system.

During 1983/1984, a new approach to reverse osmosis was demonstrated on minewater from the East Rand Proprietory Mines Ltd., as described in a trip report in Appendix I, in a test program undertaken jointly by the Water Research Commission, the Chamber of Mines of South Africa, equipment vendors, and Rand Mines.

Normally, when using holofine-fibre or spiral-would R.O. membrane systems, various solution pretreatment systems are required. When gypsum-containing minewater is to treated, then a very large pretreatment may be needed ahead of a small R.O. Plant. The new technology employs a tubular R.O. system which is considerably more bulky for the same job than the more sophisticated types of R.O., but it avoids, altogether, the need for water pretreatment.

By recycling precipitated sludges consisting mainly of gypsum, SiO_2, and alumina through the tubular R.O. system in much the way way as for cross-flow filtration (as described above), a high yield of product water can be obtained. Suspended solids in this particular test case where dropped from 50 mg/l to less than 1 mg/l in the permeate (product) water. Precipitate solids content of the sludge in the recirculating stream of concentrate was 4.5%, but this would be increased perhaps tenfold by allowing the concentrate solids to settle out.

Seeded slurry R.O., therefore, demonstrates a highly efficient means of removing not only dissolved solids, but also suspended solids.

Not for one minute would a relatively capital intensive process such as R.O. be recommended for removal of suspended solids, but this aspect is one more plus factor favoring its use in dissolved contaminant removal.

The seeded slurry reverse osmosis process is patented and under further development by:

MAGNETIC FILTERS

Magnetic filters as a means of removing very minute suspended particles from treated effluents have been discussed and researched for several years. To date, no commercial installations using magnetic filters for this application have been identified. However, considering the tremendous progress made in ultra high strength magnetic fields, as well as very much stronger permanent magnets, the possibility of magnetic separation of suspended precipitates from effluents should be considered a potential future development.

ALLEN, et al. (1976) discussed the use of SALA-HGMS magnetic filters for the treatment of combined sewer overflow water. Suspended solids in steelmaking effluents were reduced from, in some cases, 4,500 mg/l to less than 10 mg/l through the use of 5-10 kG magnetic fields at flow velocities of 2.5-5 m/min. in single pass applications. Removal of zinc, chromium, and lead precipitates from a solution containing very low levels of each to begin with also yielded promising results and, clearly, this process has some future merit.

Information on further developments may be available from:

SALA MAGNETICS, INC.
Cambridge, Massachusetts
D. Allen

KARELIN, et al. (1975) described Russian experiments in which sludges contatining 15-20% Cr, 30-40% Fe, and Ni were recovered from wastewater using a magnetic concentrating device. Chem. Abstracts contains little detail except that the maximum effectiveness was achieved at 200-250 rpm. The addition of tall oil improved the separation 2-3% for Fe and 1.0-1.5% for Cr and Ni."

COARSE PARTICLE SEPARATION

The processes discussed above concentrate on the problem of removing fine particles from water. Sometimes it is necessary to remove coarse grit and other debris from solutions or water as a means of preventing downstream clogging of screens or abbrasion effects. These can be removed by open screen decks or sievebends, but what of particles too small to be removed by such devices.

Usually with such devices, the problem arises in determining how and when to cycle the backflush. If carried out using a timer on a timed interval, if it backflushes too often then efficiency is lost, and if it backflushes too seldom, the filter may be clogged and ineffective for part of the time.

An innovative device was designed to overcome these proglems by automatically backflushing itself on demand whenever it senses that the pressure drop across the screen has built up too high. The Filtomat device is described in the following brochure and paper by PATZ and BARNEA (1984).

In the trip report on ZINCOR in Appendix 1, one user's opinion was canvassed. They found that the Filtomat rejected too much water during the backflush step in the cycle. Other users are reputedly very pleased with their Filtomats.

There are, of course, several other ways in which grit can be removed from feedwater, process solution, and effluents.

HOW THE FILTOMAT SELF-CLEANING WATER FILTER WORKS

The filter is flanged in-line. On entering the filter, water passes through a rough screen which traps any oversized particles that might clog the workings. The water then flows to the lower section which is enclosed by a fine screen mounted on a perforated cylinder. This screen size is chosen to suit the desired degree of filtration. As dirt builds up on the screen it gives partial filtration for smaller particles as well. The bed of solids which forms increases the difference between the inlet and outlet pressure.

At a predetermined pressure difference the control pilot opens the hydraulic valve. When this happens the pressure in the flush chamber falls to atmospheric pressure. Some of the filtered water is sucked into this low pressure chamber via the hollow fin. Holes in the spin bar cause the fin to spin allowing it to clean the entire fine screen.

The dirty water is discharged through the hydraulic valve to the drain, while the main flow is uninterrupted. The cleaning cycle stops when the filter screen is clean.

The length of the cleaning cycle is about 10 seconds, the frequency depending on the nature and quantity of suspended solids being removed.

FILTOMAT

THE FILTER THAT WORKS ON WATER

FILTOMAT | THE REVOLUTIONARY AUTOMATIC SELF-CLEANING WATER FILTER FOR INDUSTRY AND MINING

The **Filtomat** embodies a new concept in water filters that has numerous advantages over presently available solutions. It offers new opportunities for removing suspended solids which up to now may have been impractical or uneconomical. These uncomplicated units are installed and function with the minimum of fuss and attention.

Filtomat filters have proved their efficacy overseas where more than 7 000 units have been installed since 1975. Local engineers have been quick to see the opportunities and in the first ten months in South Africa more than 100 units were successfully commissioned in a variety of applications. These include bottle washing, citrus packing, steel, textiles, fish growing, golf courses, plastic and rubberware manufacture and mine applications both above and below the surface.

One of the most successful applications has been in cooling towers and condensers, giving dramatic reductions in suspended solids at a fraction of the price of sand filters.

An engineer's delight - the principle of operation is ingeniously simple - and it works! The kind of obvious solution to an age-old problem that makes you wish you had thought of it yourself.

If you feel you may have an application - contact us without obligation - if your application is right, the **Filtomat** will sell itself. Where we cannot show you a successful installation, we will arrange a trial.

We believe in back-up service and offer the following guarantee:

Any customer disappointed with his Filtomat can return it during the first month for an unconditional refund of the purchase price.

We won't have an unsuccessful Filtomat in operation!

12 inch Filtomat filtering water into the underground cooling system in a mine prevents clogging of the refrigeration plant saving over 8 000 man-hours in cleaning and maintenance per year.

Description	Model Designation						
	M 303	M 304	M 306	M 308	M 310	M 312	M 314
Inlet and outlet flanges	3"	4"	6"	8"	10"	12"	14"
Installation length	604mm	748mm	910mm	1176mm	1340mm	1450mm	1532mm
Nominal flow capacity [m³/h]	40	80	150	300	400	600	900
Weight of unit	30kg	40kg	80kg	150kg	250kg	350kg	500kg

- Normal design pressure is 10 bar (150 psi) (1).
- Clear screen pressure drop at nominal flow = 0.2 bar (3 psi).
- Maximum temperature 65°C (1).

(1) Special applications may be catered for with alternate materials of construction.

LONG UNITS

For heavy dirt-loads or fine filtration special long units are available for 3", 4" and 6" pipelines. These units have larger bodies that offer between 2 to 4 times the screening area of the regular units.

FILTOMAT SELF-CLEANING WATER FILTERS OFFER ALL THESE ADVANTAGES

- **In-line** - flanges straight into the main pipeline. No support structures are needed.
- **Automatic operation** - self-flushing is automatically triggered by pressure differential.
- **No external power**- operates on water pressure only.
- **Attention-free**- requires little attention and only needs checking semi-annually.
- **Uninterrupted flow** - no interruption on the line flow during cleaning process.
- **Compact** - sturdy construction. Easy installation.
- **Positioning** - does not rely on gravity and can be installed in any position; horizontal, vertical, sloped or even upside-down.
- **Low pressure drop** - maximum pressure drop is adjustable.
- **Removes algae and organic matter** - is not contaminated by oil and other impurities.
- **Positive filtration** - can be controlled by the selected screen size.
- **High throughput** - the units can handle the full normal flow of the pipeline.
- **Competitive price** - a fraction of the price of equivalent sand filters.
- **Unaffected by fluctuating flows.**
- **Backed by the Bateman Organisation.**

FILTOMAT HAS MANY VARIED APPLICATIONS

COOLING WATER	Used in cooling towers, chiller water, heat exchangers, make-up water, to reduce the fine solids that would be deposited on heat transfer surfaces and reduce efficiency.
SAFEGUARDS EQUIPMENT	Prevents clogging of pipelines, valves and expensive equipment and reduces wear from abrasive particles.
PROTECTS NOZZLES	Keeps nozzles permanently open wherever water is sprayed even at high pressure. Removes particles that might damage the product being sprayed.
WATER RE-USE	Permits the re-use of factory water by removing contaminated particles.
PROCESS WATER	Removes undesirable solids from process water. Permits collection of desired particles as flush water can be collected.
IRRIGATION	Removes solids and sediments, clarifies supply water in drip, spray and sprinkler systems. Filters water from sewage farms.
WATER SUPPLY	Removes algae, dirt, sand and silt from boreholes, rivers and dams; removes sediments and rust and prevents the clogging of water meters and pipes. Reduces the quantity of chemicals required to treat potable water.

6 inch unit installed over sump in a cable factory filters PVC, rubber, grease oil and algae and prevents valves, nozzles and pipelines from blocking, saving thousands of Rands and man-hours in maintenance and downtime.

12 and 10 inch units used in agriculture remove sediment and solids and clarify the supply water for spraying and sprinkling.

APPLICATION OF AN IN-LINE SELF-CLEANING WATER FILTER IN THE MINING INDUSTRY

1. INTRODUCTION

Water is extensively used in the mining industry: for mining itself, as a medium for ore transportation and physical processing of the ore (wet milling etc)

- as a medium for chemical processing of the ore (whenever hydrometallurgy is involved),
- for cleaning (of spillages, machinery, belt conveyors etc.),
- for service to process (steam generation, liquid ring vacuum pumps, hydraulically operated valves and equipment, cooling of machinery and engines etc), and
- services to operating manpower (temperature conditioning in deep mines, air-conditioning of offices, washing, cooking, drinking etc.).

Part of the water will normally be kept in closed cycle, other parts will be consumed in the process and they will have to be supplied from primary sources like: wells, rivers, dams, national networks etc.

In nearly all cases, water will be contaminated by suspended solids to a larger or smaller extent. These may originate from the primary source of water (sand algae, large organisms like flies, small fish, mosquitoes, grass, woodchips, dust etc).

In recycled water solids may be present as a result of rust, scale, dust, finer fractions of ore etc. The presence of such suspended solids can seldom be considered desirable, however, in many cases the application as such and the problem associated with suspended solids is relatively small and not worth the cost of elimination.

In other cases, effort to eliminate or at least reduce the extent of the presence of these solids is justified or even imperative as the solids contribute to higher maintenance costs (e.g. by abrasion, fouling of heat transfer services, breakages of pipelines, nozzles etc., fouling the sealing action of valves etc.) and in certain cases, interferes with the process itself. (This occurs mainly whenever water is to be sprayed with relatively fine nozzles such as for instance, cake washing on filters, washing of conveyor belts and filter cloth etc.).

Further there are many cases where the reduction of the level of suspended solids would be desirable, were a convenient and economical means available. At present the problem is being lived with either because the decision-makers are unaware of a solution or because the direct and indirect costs of the problem are underestimated or not well-appreciated.

In this paper we shall introduce a new concept of elimination or reduction of suspended solids in water, which represents in many cases an ideal solution to the problem, and describe one such available system.

In order to clearly define the scope of problems that can be solved by the application of this new concept, it should be stated here that the upper level of suspended solids that can be economically treated by the Filtomat, is about 1000 ppm (it may be higher than that, say 3000 ppm in the case of relatively coarse solids to be eliminated) and the minimum particle size that can be eliminated is about 30 - 50 micron in the case of an open cycle (finer particles will also be eliminated or reduced in quantity, but 100% elimination is obviously determined by the size of the opening in the filter cloth or screen).

There is no lower limit in the case of water circulating in closed cycle as is described in the text.

Existing Technology

The simplest filters are of the disposable cartridge type where the filter elements are dispensed with when they become clogged. Also at the simple end of the scale are cartridge filters and hand strainers that are cleaned manually for reuse. While they are inexpensive to manufacture they demand constant attention and as such their operating cost is high. In the case of disposable cartridges, the cost of replacement cartridges also contributes to operating costs. As these units block up, they cause a growing pressure loss until they are cleaned. Thus the process downstream is subjected to variable pressure.

The so-called automatic strainers are operated by timers and auxilliary motors. These require a source of energy which adds to the complexity and expense of the installation. Such a source is also subject to failure. The timing device is unaware of the quantity of dirt in the strainer, and is set to flush the unit at regular intervals. The quantity and nature of solids in the water can vary, typically by orders of magnitude, and to cope, the timer must be set for the worst possible case. Therefore, the unit will flush in most cases well before it is necessary with an associated waste of flush water. Should an unusual quantity of solids come through the system, the unit is susceptible to being blocked.

Sand filters are capable of filtering suspended solids down to very fine sizes. However, they are large in size and expensive for large flows. For underground installations, the size becomes a problem. They also involve a relatively large indirect investment (civil and structural) to make the overall investment even higher.

They require attention as they have to be backwashed and they flush fairly large quantities of water. While they are being backwashed there is an interruption in the flow of water. Those that are automatic suffer from the same weak point with regard to the timer as described earlier. In addition sand filters are susceptible to contamination by oil and other chemicals.

The pressure drop across sand filters is considerable.

In contrast to strainers, there are cyclones. They are units that extract a portion of the solids by centrifugal force. They contain no moving parts, being operated by water pressure. These units have no positive straining so the filtration is of a statistical nature.

Therefore the unit does not provide a 100% protection for nozzles, but merely reduces the frequency with which they block up. Cyclones have a relatively large pressure drop especially if the removal of fine particles is required. They waste a lot of water in a continuous flow. If the units are adapted to collect the dirt, they require frequent manual cleaning. It is difficult to install cyclones for large applications as this requires many units in parallel. Cyclones are set to operate optimally at a specific pressure and any variation from this pressure will reduce the efficiency of the unit.

Requirements for an Ideal Strainer

From the above considerations, it can be seen that a strainer incorporation most of the advantages of the different systems described and avoiding most of the problems would be of great value to the mining industry.

What is ideally required is a unit with the following characteristics:

1. In-line - so that it can fit in as an intergral part of the process and not require water to be diverted. In-line filtration also implies low installation costs as no civil or structural work is involved;

2. Automatic operation activated by some feedback system which senses when the unit requires to be flushed. This not only eliminates unnecessary flushing, but ensures that the unit will react to sporadic high loads;

3. No power requirement - operating on water pressure alone;

4. Minimum maintenance and attention required;

5. Low pressure drop, thereby reducing energy requirements;

6. Positive straining - it is important that the unit be capable of giving 100% protection at a given cut-off point. The cut-off size itself should be as small as may be required for the particular application.

7. Uninterrupted flow - while the unit is flushing. It is desirable that the flow of water to the end use be uninterrupted. This would also reduce the necessity of having stand-by units or an automatic by-pass;

8. High throughput - Ideally a single in-line unit should be able to treat the throughput handled by the pipe.

9. Ability to be installed in any position to eliminate stereometrical constraints that are particularly severe in underground installations;

10. It would be desirable if the solids were ejected in concentrated form such as a wet-cake;

11. Relatively cheap - this is a self-evident advantage.

Some further advantages of the unit would be:

If the unit is triggered by the actual amount of dirt in the system, it is possible to ensure that the headloss due to the build-up of dirt never passes a maximum predetermined amount.

If the unit flushes itself, it can be made fairly compact as the screen can be cleaned at fairly frequent intervals and need be no longer than required to absorb dirt that would collect in less than an hour.

There are known in the art a great number of fluid cleaning devices which include one or more brushes which are adapted to scrape the surface of the filter member either manually or automatically by means of an auxilliary water motor pump. These devices suffer primarily from the drawback of poor cleaning since the brushes do not effectively loosen and free the dirt stuck in the filter's smaller holes. Moreover, such an arrangement calls for auxilliary driving motor which adds to the cost on the one hand and reduces the situations in which such a filter can operate on the other.

The objective of designing a self-cleaning filter would be to devise an effective method which overcomes the above and other disadvantages.

In order to free such a system from the requirement of external energy, it would be necessary to utilise the energy of the water flowing inside it to actuate the cleaning action and if required, this energy would be used for imparting motion to any cleaning body.

The unit would require some mechanism for sensing the load of dirt actually in the unit in order to trigger the flush and a separate flushing system that would not interfere with the main operation of the filter.

Description of the Filtomat Unit

Figure 1 illustrates one such embodiment of the above concepts - The Filtomat unit. In this particular example the unit has a steel cylinder housing (1) with flanged inlet (2) and outlet (3). A metal cover (4) is securely fastened to the housing by means of bolts and wing nuts, which allow easy removal when necessary.

It is necessary to protect the workings of the filter from outsized particles that could damage or jam them. Therefore, the raw water entering the filter under pressure is passed through a perforated plastic cylinder which acts as a coarse grid (5) and strains the large particles from the water. In order to prevent the water from flowing directly to the outlet, a steel ring (6) seals the raw water compartment from the strained water interior.

The water then enters the lower compartment which is enclosed by another perforated plastic cylinder, lined with a fine corrosion resistant screen (7), the size being chosen for the particular requirement (stainless steel screens are commercially available down to approx. 50 micron at this point in time.)

The screen is rigidly attached to the plastic cylinder. No particles larger than the screen openings can pass through the screen and reach the outlet of the unit.

The unit can be visualed as being divided into four chambers, as marked in Roman numerals on the diagram. The highest pressure is in Chamber I where the water enters. The water passes through the coarse grid (5) deposits any outsize bodies and enters the Central Chamber II. The pressure in Chamber II is virtually that of Chamber I as there is hardly any pressure drop across the coarse grid. Should a significant pressure difference be recorded between these two Chambers, this would indicate that the coarse grid had in fact become blocked and required cleaning.

After being filtered on the fine screen, the water passes to Chamber III which contains the clean water. The difference in pressure between Chambers II and III is equal to the pressure drop across the fine screen. Initially this is very low but as the solids accumulate they form a fine bed which increases the pressure difference.

The control unit can be set to flush at a specific difference in the range 0.2 to 0.7 bar. The control unit (Figure 2) contains a diaphragm with incoming and outgoing water below and above respectively. The clean water is assisted by a spring. At the predetermined pressure difference the equilibrium of the diaphgragm is upset and this activates the unit, causing the hydraulic flush valve to open.

Up to this point the pressure of the water in Chamber IV has been equal to that of Chamber II, to which it is connected solely via a hollow fin and shaft (10, 11). When the flush valve opens, the pressure in Chamber IV falls to atmospheric pressure. It is imperative for the good operation of the system that at this point the pressure in Chamber IV be much lower than those in Chambers II and III (about 40%). This requires that the minimum pressure in the main line be approximately 2 bar.

When this happens, some of the clean water from Chamber III is sucked into the fin (10) and evacuated out through the flush valve. In so doing it cleans a section of the fine screen. From the hollow fin (10) the suspension of dirt in the water flows through the hollow shaft and the spin bar (11). The positioning of the holes in the spin bar (11) directs the water to be ejected in a tangential direction which imparts rotational motion to the entire hollow fin, shaft and spin bar system (as in a rotary sprinkler). The rotating fins (10) thus cover the entire area of the fine screen. The duration of a flushing operation is approx. 5 seconds and while it is taking place the main flow is uninterrupted. On all the larger units, the screens are longer. In order to cover the screen area the fins require an axial movement in addition to rotation. This is provided by a piston that is also actuated and operated solely by the water pressure.

When the filter screen has been cleared, the cleaning cycle stops until the pressure difference between Chambers II and III again reaches the preset amount. The frequency of flush depends on the quantity of suspended solids and varies typically between minutes and days.

Initially the only filtering medium is the stainless steel fine screen. As the dirt collects on the fine screen a cake is slowly built up. This contributes to the filtering process and progressively finer particles are filtered out. Eventually towards the end of the cycle, just before flushing, very fine particles are taken out. A typical example is shown in Figure 3.

When the water is reticulated in a closed cycle operation (such as in a cooling water system) such a cake is capable of filtering down to a few micron in size. Fine solids that passed through the screen at an earlier cycle are trapped on a subsequent one.

The size of the fine screen will depend on the particle size distribution. It is sufficient that only a small percentage of the particles are larger than the screen size for a cake to be initiated. In order to allow a good cake to be built, one chooses the coarsest screen that will operate effectively.

In such a system very fine particles such as dust, slime and fine algae are separated from the water, safeguarding clean water in the tower and preventing sediments on the pipe walls.

When filters are initially installed into an existing closed circuit, they flush very frequently until the residual dirt is extracted. This may take one or two days of operation. The cycle slowly lengthens until equilibrium is reached, whereby the quantity of solids extracted per flush equals the quantity of dirt entering the system between flushes.

Technical data of the various models are given in Table 1.

To what degree does such a unit meet the abovementioned requirements:

1. In-line
   This configuration is flanged straight into the main pipe and requires no civil or structural supports;
2. Automatic Operation
   The unit operates automatically by its control unit which senses via the pressure drop that the unit requires flushing;
3. No Power Required
   The unit utilises the pressure of the water for all its operations and requires no external power. There is, however, a lower limit of about 2 bar and in systems with less than this, the units do not always operate satisfactorily. This should not be confused with the pressure drop which is low (see 5. below and also Table 1);
4. Maintenance Free
   The unit requires no attention and only needs checking on an annual basis;
5. The Pressure Drop across the screen depends primarily on the flow of water through it rather than on the screen size. At nominal capacity the pressure drop is relatively low (see Figure 4). The maximum pressure drop (across the screen plus the built-up cake just before flushing) is adjustable at will in the range of 0.2 to 0.7 bars).
6. Positive Straining
   The unit has positive straining for a given size of fine screen. In addition as dirt builds up on the screen, it gives partial filtration for smaller particles. A 100% retention of particles smaller than 30 micron in an open cycle is, however, currently impossible.
7. Uninterrupted Flow
   The unit has a separate flushing system and the main flow is left uninterrupted during flushing. During flushing, about 40m³/hr. of additonal flow is added.
8. High Throughput
   The largest unit currently available is capable of treating 1000m³/hr. on a 14" pipeline. Larger units of higher capacities are being developed.
9. Positioning
   As gravity does not play a role in the operating principle the unit can be installed in any position: horizontally, vertically, sloped or even upside-down.
10. The Filtomat cannot discharge the solids in the form of a cake, however, it does use less water than sand filters or simple cyclones.
11. Price
    Small units are expensive relative to hand cleaning and manual flushing systems, but large units are a fraction of the price of sand filters.

Practical experience in South Africa in the Mining Industry

As the unit is fairly new to South Africa, the number of operating units in the Mining Industry is relatively small while a number of units are in the process of being installed. The following two examples are quoted as they have been running for periods of 4 to 6 months which allow conclusions to be drawn.

Two 8" units were installed in an underground cooling system in February this year. The full throughflow was approximately 900m³/hr. The fine screen size was 400 micron with a small section of 200 micron. The suspended solids in the condensor water dropped from 45 ppm to less than the level of detection which was 2 ppm. On the first day, the filters flushed a few times per hour, settling down to an equilibrium flush of once per shift. With reference to the cleaning of the unit, the cost of manpower and material was also significantly reduced.

At Winklehaak Mine, initially a 12" to which was added a 10" unit were installed to protect the cooling plates of an on-surface cooling tower, the holes of which were being blocked by grass and flies. This necessitated daily cleaning of the plates. Subsequent to the installation, no cleaning was required.

There are numerous ways by which to remove or recover dissolved solids from aqueous solutions. Some of these are selective, while other are not.

MOTIVATION

Objectives in the removal of dissolved solids from solution include:

- Profitable recovery of an incremental, marketable resource. Here a selective way of concentrating a valuable species is needed.

- Removal of undesirable contaminants so that they can be discharged within effluent permit limits.

- Removal of undesirable contaminants allowing recycle solutions to be returned to the process without undesirable interferences.

- Desalination of water for use as boiler feedwater or in special processes requiring low salt levels.

TECHNOLOGIES

Several different technologies are available for the removal of dissolved salts from mine and mill effluent solutions. These are briefly reviewed by heading to illustrate the menu of tools available. In the chapters that follow, many of the most common contaminants are discussed one at a time, and the use of various processes is discussed for specific applications.

Precipitation -

Hydroxides:	Lime, Caustic Soda, Ammonia, Soda Ash
Sulfides:	
Carbonates:	CO_2, Na_2CO_3
Sulfates:	$BaSO_4$, $PbSO_4$, $CaSO_4$

Coprecipitation -

$$BaCl_2 + Ra + SO_4 = Ba\ Ra\ SO_4$$
$$Fe^{+3} + 5OH^- + M^{+2} = (M\ Fe)\ (OH)_5$$

Desalination -

Reverse Osmosis, Seeded Slurry R.O.
Electrodialysis Reversal
Evaporation
Ion Exchange

Specific Ion Removal -

Ion Exchange
Electrolysis
Biological Metal Removal
Insoluble Starch Xanthates
Cell Wall Adsorption Media
Devoe-Holbein Media

PRECIPITATION

- Precipitation processes are the most widely used for removing species from water.
- Precipitation as hydroxides is achieved by adding lime $Ca(OH)_2$, sodium hydroxide NaOH, ammonia NH_4OH, and soda ash Na_2CO_3.
- The lime-soda softening process uses precipitation to remove sulfate ions as a means of softening water.

- At very high pH values, i.e., high concentrations of hydroxide, some metal hydroxide solubilities increase again due to hydroxide complex formation, e.g., $[Al(OH)_4]^-$, $[Zn(OH)_3]^-$, $[Fe(OH)_4]^-$, $[Pb(OH)_4]^{-2}$, etc.

- Usually, more than one species must be removed by the treatment process. Various metal hydroxides have minimum solubilities at different pH values.

- At high pH in the presence of carbonate ions (atmospheric CO_2), some metals precipitate as insoluble carbonates, e.g., $PbCO_3$.

- Several metal sulfides are less soluble than their hydroxides. Addition of sulfide ions (Na_2S or NaHS) can achieve lower levels of these metals in effluents than is possible by hydroxide addition.

TABLE OF SOLUBILITIES
ppm in Pure Water

Metal	As Hydroxide	As Sulfide
Iron	5×10^{1}	1×19^{-4}
Zinc	3×10^{2}	1×10^{-6}
Cadmium	3×10^{0}	1×10^{-8}
Nickel	7×10^{-1}	6×10^{-8}
Copper	2×10^{-2}	2×10^{-13}
Lead	2×10^{0}	6×10^{-9}
Mercury	6×10^{-4}	1×10^{-21}
Silver	2×10^{1}	4×10^{-12}
Chromium	1×10^{-3}	(No Precipitate)

- In some cases, although sulfide is added, a metal hydroxide may be precipitated:

$$CrO_4^{=} + FeS + 4H_2O = Fe(OH)_3 + \underline{Cr(OH)_3} + S^0 + 2OH^-$$

- Effluent contaminant levels and flowrates vary. Since excess sulfide in treated effluent is undesirable, this process never became popular. Also, extremely low metal levels have only recently been required as effluent discharge criteria. The addition of FeS as a source of sulfide is a practical answer which is innovatively applied in the Sulfex process of Permutit Co., New Jersey, as described in EPA (1981) at the end of this chapter.

- Metal sulfide solubilities are pH dependent.

CALCIUM AND BICARBONATE SOLUBILITY VS pH

Source: HEM (1970)

—Equilibrium pH in relation to calcium and bicarbonate activity in solutions in contact with calcite. Total pressure 1 atmosphere; temperature 25°C.

Precipitation of heavy metals as hydroxides

Fig. 1

- Hydroxide precipitates are often gelatinous and difficult to filter or settle. Some sulfide precipitates are very finely divided and also difficult to filter or settle from solution.

- Metal hydroxide precipitates are amphoteric, i.e., if the pH is lowered again, they will go back into solution.

- Some metals from sulfide complexes which are less soluble than simple sulfide compounds--in the presence of excess sulfide, some metals go back into solution.

- $CaSO_4$ is soluble up to 2,000 mg/l beyond which it is likely to precipitate a scale unless the solution is stabilized by reagent addition. More often than not, gypsum precipitate as scale causes problems in metallurgical processes. Clever use of slurry seeding can made gypsum precipitate in a way that avoids scale formation.

- The eH of solutions and temperature affects precipitation processes as does the composition of the solution. $CaSO_4$ solubility and crystal structure are particularly temperature dependent.

- Co-precipitation is a powerful phenomenon used, for example, in the removal of radium which co-precipitates as $BaRaSO_4$ when $BaCl_2$ is added to solutions containing sulfate ions. Co-precipitation also occurs when ferric hydroxide is precipitated--for example, lead, arsnic, and selenite ions are amongst several that co-precipitate with iron. Manganese oxides and hydroxides co-precipitate radium and manganese from solution. In the seeded slurry process, gypsum co-precipitates silica and a host of other cations.

- Limestone has been used to precipitate silica from recycled solutions during which chloride levels are also reduced in a South American copper plant solution.

- Some precipitates are not stable when in contact with naturally occurring CO_2 (H_2CO_3) in water, e.g., $Ba_3(AsO_4)_2$ and $FeAsO_4$ convert to the $BaCO_3$ and $Fe_2(CO_3)_3$ when exposed over a long period of time to water in equilibrium with atmospheric CO_2. Possibly reduction of pH to 6.5 by H_2CO_3 plays a role here.

- Oxidation state of elements can have a profound effect on their solubilities, e.g., Fe^{2+} or Fe^{3+}, As^{+3} or As^{+5}, Cr^{+3} or Cr^{+6}, Se^{+4}, or Se^{+6}, etc.

- Complexing agents such as humic acids, cyanide, ammonia, etc. can interfere with hydroxide precipitation. Where precipitate compounds, e.g., sulfides, are more stable, then precipitation withdraws the metal ions from the less stable complexed form. For example, FeS added to copper cyanide precipitates <u>CuS</u> and ties the cyanide up as $[Fe(CN)_6]^{-4}$.

- Salt balance modelling, except in the simplest possible cases, is very complicated because of the many interrelated effects.

- In evaluating the cost of treating effluents by precipitation processes, the following items must be taken into account:

  1. pH adjustment reagents before, during, and after precipitation.
  2. Reagent costs, e.g., sulfide addition or oxidizing and reducing agents.
  3. Cost of recovering the precipitate, i.e., solid/liquid separation.
  4. Cost of precipitate sludge dewatering.
  5. Cost of disposing of the precipitate sludge safely and legally.
  6. Cost of polishing the solution after primary solid/liquid separation.

- The relative cost of various precipitation processes are so site specific that no generalizations can be made. A systems approach must be adopted to evaluate all alternatives.

- There are several highly innovative new techniques for reagent recycling, solid-liquid separation, enhanced precipitation techniques, etc., e.g.,

  - Jet Pump Oxidation and Precipitation
  - High Density Sludge Process
  - X-Flow Microfiltration

  These are discussed in Chapter 24 on Acid Mine Drainage treatment and Chapter 25. X-flow microfiltration is discussed in Chapter 12 on removal of suspended solids above.

DESALINATION

Desalination processes remove (or recover) all ionic and suspended species contained in feedwater to a concentrate, while producing water essentially free of dissolved or suspended solids. Several desalination processes involve membranes. Others involve ion exchange resins, while a third category of desalination is evaporation.

The RANDOL study concludes that desalination processes should, if at all possible, be avoided in mine-mill complexes. Desalination should be considered only when all else fails and even then, the simplest systems should be given priority. Some successful desalination plants are operating on metallurgical process effluents using R.O. followed by evaporation (distillation) for final water recovery from the R.O. concentrate stream.

Desalination (R.O. and evaporation) is employed for the recovery of potable water from seawater at large installation in the Middle East, Florida, and Malta, as well as in smaller installations on oil drilling platforms, trawlers, and naval vessels. Although these operations start with seawater containing over 30,000 mg/l TDS, in these installations recovery is inconsequential, and disposal of the concentrate is of no concern. The objectives of such systems are not comparable with those required to treat mine and mill effluents.

MORRIS (1982) compared the energy requirements for various desalination processes as follows:

Primary Energy Form	Process	Energy Required kWh/m³		
		Commercial	Demonstrated	Conceptual
Heat	Distillation	25	15(1)	15
	Freezing	--	27(2)	15
Electrical	Electrodialysis	--	13(3)	9
Mechanical	Distillation	20	15(4)	10
	Freezing	--	11(5)	8
	Reverse Osmosis	10	7(6)	5

Heat to kWh was converted at 33 1/3% conversion factor.

(1) 1 Mgd OSW test bed plant at San Diego, California, R&D Report 666.
(2) 15,000 gpd pilot plant, Wrightsville Beach, North Carolina, R&D Report 113.
(3) Projected value, plant under construction, Wrightsville Beach, North Carolina.
(4) 1 Mgrd OSW test bed plant, Roswell, New Mexico, R&D Report 170.
(5) 60,000 gpd pilot plant, OSW Wrightsville Beach, North Carolina, R&D Report 295.
(6) Small commercial units - Piston Pumps.

From the above, it is clear that from an energy efficiency standpoint, R.O. and electrodialysis are the most favorable of the commercially demonstrated desalination systems.

The 20,000 m³/d seawater desalination plant installed at Ghar Lapsi, Malta, using DuPont Permasep holofine fiber R.O. modules consumes 6 kWh/m³ energy. This plant was commissioned in 1983 showing how quickly the technology is developing. Only a year before, the U.S. OWRT reported 10 kWh/m³ as the best commercial performance, and 6 kWh/m³ as the conceptual optimum.

A potentially interesting source of information on reverse osmosis is an SRI multi-client study: Business Opportunities in Membrane Separation.

An excellent review of "Desalination Processes from a South African Perspective," which includes desalination of acid mine drainage, is provided by SCHUTTE (1983) in a report available from:

WATER RESEARCH COMMISSION
Post Office Box 824
Pretoria 0001,
South Africa

C. F. (Frik) Schutte is a senior advisor to the Water Research Commission and is currently on sabatical in the U.S.A. The Water Research Commission and the South African mining industry are deeply involved in finding ways to avoid or treat acid mine drainage and today have access to the most comprehensive compilation of experience in desalination of mine-mill effluents, togethr with the vendors whose equipment was demonstrated. Of these, Resources Conservation Company whose address is shown below is probably the leader in this specialized application of desalination.

ANDREWS, et al. (1983) reported costs of the seawater reverse osmosis desalination facility installed by his company, Polymetrics, Inc., at Ghar Lapsi, Malta, which treats 20,000 m^3/d. Inquiries can be directed to:

Amortization	$0.43
Total	$1.08

Tom Sackinger at the Desalination Conference held in Florence, Italy, in 1983, estimated the cost of seawater desalination, based on a 12% per annum membrane replacement, as follows:

R.O. Costs: Seawater

Energy @ 7.4 kWh/m³	$1.80
Chemicals	0.14
Labor	0.19
Maintenance and Repairs	0.86
Amortization	1.75
Total	$4.96 per 1,000 U.S. Gallons

REED, S.A. (1982) and SCHUTTE (1983) report useful cost data and comparisons for various desalination processes. A further set of cost data was compiled by GLUECKSTERN (1982). Randol International Ltd. has a copy of each of these documents, and copies could be made available to sponsors on request. In addition, companies such as the RESOURCES CONSERVATION COMPANY and CH2M Hill also are continuously involved in updating costs of desalination. These contacts can be reached as follows, but it emphasized again that the real costs of desalination must include the cost of disposing of the concentrates produced which is not generally figured into desalination cost comparisons, and cost data for seawater desalination are not particularly applicable for acid minewater or metallurgical effluent treatment use of desalination processes.

SYNTHETIC MEMBRANE PROCESSES
Fundamentals and Water Applications

Edited by

GEORGES BELFORT
Rensselaer Polytechnic Institute
Troy, New York

A Volume in the WATER POLLUTION Series

October/November 1983, c. 510 pp.,
in preparation/ISBN:0-12-085480-5

The latest theoretical developments in membrane and fluid transport and synthetic membrane treatment processes are analyzed in this well-designed work. Contributions by international experts consider the subject from the perspective of the chemical engineer and provide a valuable integration of theory and practical applications. The chapters review the fundamentals of hyperfiltration, ultrafiltration, and electrodialysis; summarize the experience with these processes in treating water and wastewater: examine the design and operation of membrane plants now established in the United States, Japan, and Europe; and analyze current economic considerations involved in the implementation of membrane processes. The volume also covers pretreatment, membrane cleaning, and fluid management for the reduction of the degradation effects of membrane fouling.

Synthetic Membrane Processes: Fundamentals and Water Applications will prove invaluable for those in the water and wastewater treatment fields, and for readers interested in the adaptation of membrane technology to new separation or concentration applications.

Table 1: Various membrane separation processes[a)]

Process/Concept	Materials passed	Driving force	Material retained
Microfiltration 	Water and dissolved species	Pressure difference, typically 10 psi	Suspended material (silica, bacteria, etc.). Variable particle-size cutoffs
Dialysis 	Ions and low-molecular weight organics (urea, etc.)	Concentration difference	Dissolved and suspended material with molecular weight > 1000
Electrodialysis 	Ions	Voltage, typically 1 to 2V/cell pair	All nonionic and macromolecular species
Reverse osmosis 	Water	Pressure difference, typically 100 to 800 psi	Virtually all suspended and dissolved material
Ultrafiltration 	Water and salts	Pressure, difference, typically 10 to 100 psi	Biologicals, colloids, and macromolecules. Variable molecular weight cutoffs
Gas separation 	Gases and vapors	Pressure difference, 1 to 100 atm	Membrane-impermeable gases and vapors

a) H.K. Lonsdale, J. Membrane Science, 10, April 1982, p. 81-181.

MEMBRANE SEPARATION TECHNIQUES

R.O., ED, and EDR processes all use membranes but in different ways. The table from LONSDALE (1982) summarizes the family of related membrane separation technologies. Between R.O. and ED/EDR, there is a very important difference. In R.O., water permeates the membrane; in ED/EDR, ions migrate through the membrane.

REVERSE OSMOSIS (R.O.)

- Water is forced under pressure through a membrane in a reversal of the natural osmotic migration of water across membranes from concentrated to less concentrated solutions on either side of the R.O. membrane. To achieve this, an external pressure is applied to the feedwater side of the membrane. This pressure must exceed the osmotic pressure for the given concentration difference.

- Osmotic pressure across a membrane is proportional to the concentration difference of the solutions on both sides of the membrane.

- Rate of solution transfer through R.O. membrane is proportional to the surface area of the membrane. To obtain a good flux rate for a R.O. module, designers have resorted to very high surface area systems such as spiral wound and holofine fiber systems. These large surface area systems can produce 80 m^3/d from a 1 m long module compared with only 1 m^3/d from a tubular membrane system of comparable size.

- Holofine fiber and spiral wound membranes are very sensitive to fouling by precipitates that form on the membrane surface from scaling solutions and/or organic fouling. This necessitates very extensive water pretreatment steps which may exceed the cost of the desalination equipment when this type of R.O. module is used. There is a limit to the recovery that is possible from scaling solutions using holofine fiber and spiral wound membrane modules due to $CaSO_4$ and $Fe(OH)_3$ fouling unless a multiple pass arrangement is used with pretreatment between each pass which would be most impractical and energy intensive.

- Th use of tubular R.O. systems, although many more modules may be needed for the same water production, saves the need for pretreatment and has been demonstrated to be capable of recovery in excess of 95% of the feedwater from a highly scaling $CaSO_4$ containing feed when the innovative new seeded slurry R.O. process is applied.

- There are several new membrane materials in addition to the original cellulose-acetate which is stable within limited pH and temperature ranges. Significantly improved membranes made from sulfonated poly sulfones, for example, and composite membranes containing polyamides are now becoming available.

- Reverse osmosis is an emerging technology, and there are steady improvements as well as more experience accumulating in its application.

- Reverse osmosis modules present a way of bringing water into contact with a membrane and of collecting a product and concentrate solution. R.O. systems, however, require a pump to deliver pressure, piping, valving, and a pretreatment system, as well as provision for recycling solutions in a R.O. water treatment system.

- Typical applications for reverse osmosis are:

  - Demineralization of boiler feedwater.

  - Providing potable water for mines and mills.

  - Desalination where species such as Na, $CaSO_4$, Cl^-, NO_3^-, etc. cannot be removed by conventional means.

  - There are some cases where reverse osmosis may be contemplated as a concentrating device, e.g., to preconcentrate effluent containing $[Cu(CN)_4]^=$ and other base metal cyanides, e.g. in foul liquors, ahead of cyanide recovery.

- The application of R.O. to mine and mill water recovery problems or purification for discharge is technically and economically feasible at a cost of around \$0.30-\$0.60/m^3 (including capital costs), but it is not a routine or easy technology. This is not yet available "off the shelf" as standard equipment.

- Reverse osmosis is installed in hundreds of operating plants for potable water recovery from seawater and brackish water in the Middle East, Malta, the Florida Keys, and on oil drilling platforms, as well as trawlers and naval vessels. In the case of seawater desalination, recovery is not a significant aspect, nor is the disposal of the resultant brines generated, even though the TDS of the feedwater is much higher than typical mine-mill effluents.

- Additional data on R.O. technology, membrane suppliers, and some cost data, as well as sources of expertise and examples of installations, are provided in Chapter 15.

ELECTRODIALYSIS (ED) AND ELECTRODIALYSIS REVERSAL (EDR)

- Electrodialysis and electrodialysis reversal differ from reverse osmosis in that in this case, ions are forced to migrate through a specially designed ion exchange-type membrane by applying an electric field across the compartment containing the feed solution. Cations migrate through the membrane on one side of the compartment to the cathode side, and anions migrate through the membrane on the opposite side, thereby deionizing the solution in the compartment between the membranes.

- In EDR, the polarity of the cell is reversed cyclically with the result that cations and anions migrate through both membranes.

- Gypsum, manganese, and iron cause fouling problems on EDR membranes. Iron and manganese cam be removed from recycled concentrate by precipitation. Gypsum must be sequestered using reagents but, because of limits in the concentration of gypsum that can be kept in solution (2-3x saturation), there is a limit to recovery of water from gypsum-containing solutions.

- A demonstration EDR plant was installed at the ERPM mine in South Africa to desalinate minewater. The EDR stack was compact, but it was hooked up to a large pretreatment plant, and there was evidence of a battle with gypsum problems.

- A very large ED plant was operated in the 1960's to treat mill tailings recycle water at one of the Orange Free States' gold mines near Welkom, South Africa. Problems and performance at this plant could prove useful if a source of information could be found, although EDR technology has made tremendous advances since then.

- There are two main suppliers of ED and EDR systems in the world, namely IONICS, U.S.A., and the ASAHI CHEMICAL CO., Japan. Their addresses are shown in Chapter 16 on EDR below.

DESALINATION: A SOUTH AFRICAN PERSPECTIVE

PRETORIA
SEPTEMBER 1983

CHAPTER 11 ECONOMIC CONSIDERATIONS

11.1 Introduction

Numerous cost estimates, cost projections and cost comparisons for the desalination of seawater and brackish waters by the various desalination processes have been and are being prepared and published by various organizations and companies. One of the most authoritative of these is the "Desalting seawater and brackish waters : 1981 Cost Update" prepared by the Oak Ridge National Laboratory for the Office of Water Research and Technology, U S Department of the Interior. ORNL/TM 8191 (Reed 1982).

This cost update (and three earlier cost estimates) by the Oak Ridge National Laboratory operated by Union Carbide Corporation, has become the standard cost reference for cost projections and cost comparisons in the world desalination community. The discussion in this chapter and most of the cost figures are based on ORNL/TM 8191 unless otherwise stated.

No provision is made in these estimates for brine disposal costs other than for construction costs for brine outfalls. Any other disposal costs should be added to the figures presented herein.

11.2 Basis for cost estimates

(i) Costs are based on second quarter 1981 installed equipment costs in USA dollars for installation in the USA.

(ii) Plant load factors of 85% for seawater and 95% for brackish water systems have been assumed.

(iii) Membrane lifetime for reverse osmosis has been assumed to be 3 years and for electrodialysis membranes 7½ years.

(iv) Cost for electricity was taken as $0,05 per kWh.

(v) Capital costs include site development, civil work associated with the establishment of well fields and brine disposal, or installation of intakes and outfalls.

(vi) Indirect capital costs have been included :
11% interest rate on capital during construction
16% capital costs for contingency and engineering and architect fees.

(vii) Costs are based on commercially available desalination equipment with standard pretreatment equipment such as chemical dosing and cartridge filtration. No provision has been made for additional pretreatment such as clarification or filtration.

11.3 Conversion to South African conditions

Figures 11.1 to 11.4 reproduced from Reed (1982) give cost figures on the basis of the assumptions in paragraph 11.2. The same assumptions also apply to figures 11.5 and 11.6 reproduced from USAID (1980). To convert these to South African conditions the following factors should be taken into account :

(i) Transport costs USA to RSA and from the port of entry to the plant location must be added to capital costs.

(ii) Import duties, surcharges and other charges must be added to capital costs.

(iii) Appropriate escalation figures for the period second quarter 1981 to the present should be added to capital costs (USA inflation).

(iv) US dollars for capital equipment must be converted to SA rands.

(v) Any fees for local agents must be included in capital charges.

(vi) Local electricity rates must be used.

11.4 Costs for seawater desalination

Figures 11.1 and 11.2 give capital and total water costs respectively for desalination of seawater by distillation and reverse osmosis as a function of plant size.

Table 11.1 and 11.2 give examples of cost calculations for a 3800 m^3/d and a 19000 m^3/d plant respectively.

11.5 Costs for Brackish water desalination

Figures 11.3 and 11.4 give capital and total water costs respectively for desalination of brackish water by reverse osmosis and electrodialysis as a function of plant size.

Table 11.3 gives examples of cost calculations for a 3800 m^3/d and a 19000 m^3/d brackish water desalinating plant by reverse osmosis and electrodialysis reversal respectively.

The reverse osmosis energy costs have been determined for 80% recovery of a feed of 5 000 mg/l TDS. This means that the energy costs in table 11.3 for a reverse osmosis plant operating on a 2 000 mg/l TDS feed is conservative by about 20%.

TABLE 11.1

SEAWATER DESALINATION

Design capacity : 3 800 m^3/d

Multistage flash (MSF) : acid treated; performance ratio 12; concentration ratio 2.

Multiple Effect Distillation (MED) : Non-acid treatment, aluminium tube evaporator.

Reverse Osmosis (RO) : Water recovery 30%; membrane life 3 years; no energy recovery.

	MSF	MED	RO
Total capital cost $/$m^3$/d	2664	2110	1412
Installed equipment cost $/$m^3$/d	1444	1105	921
Water cost $ /m^3			
Fixed capital charges @ 18% per annum	1,55	1,22	0,82
Operation and maintenance	0,28	0,28	0,20
Membrane replacement	-	-	0,26
Energy (Coal)	0,32	0,34	-
Energy electricity $0,05/kwh			0,50
Total water cost $ /m^3	2,15	1,84	1,78

TABLE 11.2

SEAWATER DESALINATION

Design capacity : 19 000 m^3/d

Multistage Flash (MSF) : acid treated; performance ratio 12; concentration ratio 2

Multiple Effect Distillation (MED) : Non-acid treated, aluminium tube evaporator.

Reverse Osmosis (RO) : Water recovery 30%; membrane life 3 years; no energy recovery.

	MSF	MED	RO
Total capital cost $/$m^3$/d	1780	1318	1163
Installed equipment cost $/$m^3$/d	934	710	794
Water cost $ /m^3			
Fixed capital charges @ 18% per annum	1,00	0,76	0,67
Operation and maintenance	0,12	0,11	0,12
Membrane replacement	-	-	0,24
Energy (Coal)	0,32	0,34	-
Energy electricity $0,05/kwh			0,50*
Total water cost $ /m^3	1,44	1,21	1,53

*This figure may be reduced by about 30% if energy recovery is incorporated.

TABLE 11.3

BRACKISH WATER DESALINATION

Reverse osmosis (RO) : Feed 2000 - 5000 mg/l : 80% recovery,
Electrodialysis reversal (EDR) : Feed 1800 mg/l, 3 stages

Plant capacity	3 800 m^3/d		18 900 m^3/d	
	RO	EDR	RO	EDR
Installed equipment cost $/$m^3$/d	158	328	138	303
Total capital cost $/$m^3$/d	318	531	254	464
Water cost $/$m^3$				
Fixed capital charge @ 18%	0,16	0,26	0,12	0,23
Operation and maintenance	0,08	0,07	0,05	0,04
Membrane replacement	0,04	0,05	0,03	0,03
Electricity @ $0,05 kwh	0,10	0,05	0,10	0,05
Total water cost $/$m^3$	0,38	0,41	0,31	0,35

Total desalinated water costs for electrodialysis reversal for a 18 900 m^3/d plant vary from $0,31/$m^3$ to $0,42/$m^3$ depending on the chemical composition of the feedwater which in turn determines the water recovery possible (80-87%) and the number of stages required for a specific production and desalination duty. The figures given in table 11.3 are for one type of feedwater and a product quality of 500 mg/l TDS.

--- oOo ---

FIGURE 11.4 : WATER COST - BRACKISH WATER DESALTING
(REED 1982)

WARNING

1. Caution should be exercised when using these cost data.

2. These costs are computed for basic desalination facilities in the USA. These costs include no storage capacity and allow for only fundamental feedwater development and brine disposal. If storage capacity is added and/or more complex feedwater or brine facilities are required, overall project costs can significantly increase. This is especially true with brackish water facilities. Construction in locations outside the USA can also add to the overall cost. Actual costs of up to 300% (or more) of those shown on this figure (especially at lower capacities) would not be unusual for projects in many developing areas.

FIGURE 11.1 Generalized capital cost estimates for desalination processes. (USAID 1980)

2. These costs are computed for basic desalination facilities in the USA. These costs include no storage capacity and allow for only fundamental feedwater development and brine disposal. If storage capacity is added and/or more complex feedwater or brine facilities are required, overall project costs can significantly increase. This is especially true with brackish water facilities. Construction in locations outside the USA can also add to the overall cost. Actual costs of up to 300% (or more) of those shown on this figure (especially at lower capacities) would not be unusual for projects in many developing areas.

FIGURE 11.2 Generalized unit production cost estimates for desalination processes. (USAID 1980)

- Several EDR plants operate in South Africa. The impressive plant at the Kriel power station, Transvaal, is described briefly in Appendix I. It pretreats Vaal River water ahead of an IX demineralization plant to take the load off the IX system. TDS is reduced from 240 mg/l in feedwater to around 50 mg/l to the IX system. Concentrate is returned to the general water supply, so this is not a valid test of yield or performance required for acid mine drainage treatment, although it demonstrates that a large EDR plant can be installed to work well and gives an impression of what such an installation looks like.

- Various experimental projects have attempted to use ED and EDR for reagent recovery in metallurgical operations, e.g., H_2SO_4 and NaOH from $(NH_4)_2SO_4$ effluents.

- Cost data for EDR application at power plants for boiler feed treatment would not be applicable to projects where ED/EDR is to be used for desalination of AMD. Although treatment of AMD containing gypsum between the EDR stages should be less expensive because EDR is not a high-pressure system, there remains the need for a complex water treatment system that is larger than the EDR plant itself.

- EDR membranes are prone to fouling, but the membrane stack can be dismantled and each membrane physically cleaned. This is, however, a laborious labor-intensive operation.

- IONICS is designing an EDR process system to yield a concentrate at 120,000 ppm TDS for use in a solar pond experiment. This is an indication that high salt concentrations can be handled by EDR under certain circumstances. These are likely to be NaCl, not $CaSO_4$ solutions however, and minewater desalination presents a different set of parameters.

- In Japan, ASAHI is said to use EDR to concentrate seawater to generate brine slurries up to 110,000-150,000 ppm salt which exits as a slurry. Very thin, efficient membranes are reputedly used.

- DE VILLIERS, et al. (1983) tested and evaluated EDR using a pilot Ionics aquamite unit to treat brackish groundwater containing 6,000 mg/l TDS at 70-80% recovery to yield a water product at 620 mg/l with overall salt rejection of 90.6%. The indicated 1982 cost was R0.69/m³ including plant amortization. Energy consumed by the EDR stack amounted to 4.6 kWh/m³.

- MELZER and VAN DEVENTER (1983) estimated a cost of EDR water recovery on a discounted cash flow basis for a plant recovering about 2 million m³/year water to be R0.35/m³ ($0.18/m³) but since this study was done by the S.A. Electricity Supply Commission (ESCOM) which used an internal power cost of R0.0167/kWh

($0.0084/kWh), this cost assessment would not be generally applicable. At U.S. $0.08/kWh, the cost of water using their calculations would be roughly double at R0.75/m³ ($0.36/m³) at this South African location treating water at 1,184 ppm TDS to produce a product of 219 mg/l TDS, yielding a reject at only 3,760 mg/l TDS of which 2,234 mg/l was sulfate.

- Capital cost in 1983 for the above EDR plant recovering 2 million m³/year was R5,200,000 ($2,600,000) which would have now to be adjusted upwards for the increased price of imported components at the devalued rand value compared to when this unit was purchased.

- The above cost estimates do not take into account the cost of disposing of concentrates.

EVAPORATION

- Evaporation/water recovery systems are commercially available and in routine use for water recovery from a variety of chemical and metallurgical industry wastewaters, some containing high salt concentrations.

- There are several different evaporation/water recovery process and equipment concepts in commercial use:

  Mechanical Vapor Recompression - Rustenburg Refiners, South Africa
  Multi-Effect Evaporators, Mechanical Vapor Recompression
  Vapor Compression Distillation - Sentrachem-Afprene Plant, Newcastle, Natal

- Evaporation/distillation is particularly competitive in treating was concentrated solutions where membrane processes and ion exchange cannot compete. For example, evaporation is one way of disposing of R.O. or EDR brines thereby yielding a dry, disposable salt and some additional water as products.

- Where there is available waste heat or low pressure steam from a power station, for example, evaporation is a highly attractive approach to desalination. For example, at the Virgin Islands' Water and Power Authority, 6 mm gpd (23,000 m³/d) of water is produced from seawater at an overall loss of 6 MW, i.e., 24 KWh per 1,000 gallons, 6.3 kWh/m³ product.

- The joint U.S.-Israeli Government project at Ashdod, Israel, which produces 37,500 m³/d water from seawater (10 mm gpd) using multi-effect evaporation, cost $10 million in 1980. Such units appear to be larger than required by the average

metallurgical plant, and metallurgical operations are not often located adjacent to power plants with waste heat.

- To avoid the loss of heat exchanger efficiency through scaling, crystal seeding is commonly applied in recirculating concentrates.

- Based on 2.5¢/kWh, which is available only in exceptional cases, the cost of vapor compression distillation of water ranges between $0.41/m³ and $0.55/m³ or $1.55-$2.08/1,000 U.S. gallons on small-scale applications.

	Std. AQ-500	Low Energy LE-500 Model
Energy Costs 2.5¢/kWh	$0.46/m³	$0.32/m³
Labor @ $3/Hour	$0.03	$0.03
Consumables	$0.06	$0.06
Total	$0.55/m³	$0.41/m³
	$2.08/1,000 U.S. Gallons	$1.55/1,000 U.S. Gallons

- The above cost breakdown allows adjustment to be made for realistic power and labor costs which indicates that at $9.00/hour labor and 7.5¢/kWH, evaporation desalination costs would be around $1.30/m³ or $4.65/1,000 U.S. gallons excluding the cost of concentrate disposal.

- The above costs refer to seawater desalination where recovery is of little consequence, and the concentrate is disposed of back to the sea. The IDE Aquaport MVC systems operate at temperatures between 30°C/55°C. Below 55°C' (130°F), corrosion and scale effects are minimized. Heating is provided by mechanical compression of the liquids. Brine is sprayed over a bundle of horizontal heat transfer tubes at a rate just sufficient to create thin, continuous liquid films. A centrifugal compressor provides suction on the outside of the tubes which enhances evaporation of the brine. After passing through a demister to prevent droplet carryover, the vapor is compressed and discharged to the inside of the tubes where it condenses, and the latent heat provides the heat required for the flash evaporation process. The product and brine leave the system via a heat exchanger which preheats the incoming feed.

- Evaporators using horizontal and vertical tubes are in commercial operation. Israeli Desalination Engineering Co. prefers horizontal tubes. Swenson, Lurgi, and the Resource Conservation Co. prefer vertical tybe evaporators.

- Special corrosion-resistant materials are used in brine evaporators. Israeli Desalination Engineering uses a unique aluminum alloy which is corrusion-resistant and has an efficient heat transfer coefficient.

- The evaporator at Sentrachem's Afprene plant, Newcastle, Natal, treats 750 m^3/d of feed with 17,000 mg/l salt content to yield 736 m^3/d product water with less than 50 ppm TDS yielding 13.4 m^3/d concentrate, i.e., 98% recovery. Power consumption is 21.4 kWh/m^3 overall of which 17-18 kWh/m^3 is for the evaporator. Feed is delivered to the plant at 20-30°C'. Overall costs are R0.85/m^3, \$.43/m^3. The system is suitable for use with gypsum seeding at which gypsum solids up to 8% are recirculated at temperatures up to 85°C'. Without seeding, the operating temperature is limited to 70°C', and a $CaSO_4$ wt percent between 0.5-1.5%.

- Innovative new welded thin-wall plate heat exchangers are available from Germany which are claimed to save energy in evaporation desalination but, to date, no commercial-scale units have been observed in mine-mill environments.

ION EXCHANGE

- Ion exchange is routinely used for demineralization of boiler feedwater for powerplants and steam plants in mines and mills. Usually, these are fixed-bed cation/anion exchanger systems.

- Ion exchange is also used for the recovery of metal ions, particularly uranium from pregnant solutions. Continuous ion exchange systems using fluid beds are employed for the most part. Popular systems in use are:

  - The NIMCIX System Developed by MINTEK, South Africa
  - Porter System and Modification Thereof
  - Old Fixed-Bed Merry-Go-Round System
  - Resin-in-Pulp Systems

- Resin-in-pulp systems are used where solid/liquid separation is impractical for recovery of values from leached ore pulps rather than from water. Continuous fluid bed systems can tolerate a considerable amount of suspended solids in feed solution. CIX systems are also routinely used at in situ leach operations.

- A continuous downflow CIX system was installed by Himsley Engineering at the Cotter Corporation's Schwarzwalder Mine for uranium recovery from minewater before it can be discharged. This system also removes several other metals from solution and achieves very low levels of uranium down to less than 10 ppb. It is described in Appendix I.

- A CHEMSEPS Higgins Loop ion exchange system is installed for molybdenum removal from Climax Molybdenum's tailings effluent, Climax, Colorado, and at WYOMING MINERALS' facility at the Bingham Canyon pit in Utah for recovery of uranium from mine drainage.

- CHEMSEPS IX systems are used for a variety of water softening applications and for nitrate removal from a fertilizer plant's wastes.

- One objection to ion exchange for desalination of mine-mill effluents is that in the elution step, more chemicals must be added. This means that in the disposal of eluant solutions, greater amounts of salt must be disposed of than were removed from solution because of the amount added in the elution process.

- In Australia, the CSIRO 'Sirotherm' process is now being tested by AMDEL for desalination of a municipal water supply that is high in NaCl content. The 'Sirotherm' process uses a resin which desorbs at high temperature and adsorbs at low temperatures. Hot water rather than chemicals is used to elute the resin which would overcome the objection of salt addition. However, it appears that this process is limited to the removal of NaCl rather than species that usually occur in mine drainage, e.g., H_2SO_4, Fe^{2+}, Ca^{2+}, Mg^{2+}, etc.

- The University of Cape Town has derived an innovative ion exchange system for desalination of minewater and effluents. Despite several interesting and innovative aspects, their system, requiring three or four CIX columns in series does not appear to be very practical for mine environments. impractical.

- In general, IX is more economical than other desalination processes at low ion concentrations. For example, in extractive metallurgy, IX is used for U_3O_8 recovery from solutions below about 200 ppm; above that level, SX becomes more cost effective. Similarly, in desalination, IX is generally competitive where very low-level ion concentrations are required, e.g., demineralized boiler feed at 10 ppm total dissolved salts produced from water with less than 500-1,000 ppm TDS, for example. Where feedwater contains higher salt levels to 10,000 ppm, it may pay to apply one of the membrane processes, e.g., R.O. or EDR. At above 1%-2% TDS levels, evaporation is likely to be the more economical approach.

FREEZING

- Freeze desalination processes, while theoretically possible, were not encountered in test programs for the treatment of AMD or other mine-mill related water treatment needs.

- DELKOR TECHNIK (PTY) LTD., Johannesburg, were investigating a method of generating ice on a large scale aiming at a reduced cost. Their idea was to combine freezing with AMD desalination and mine cooling on the Witwatersrand, but no mention has since been encountered of plant-scale tests of this idea referred to by Theo Stielan before he retired.

COMPARISON OF DESALINATION PROCESSES

Selection of an appropriate desalination process depends on the following:

- Compositon of Feedwater:

High TDS, +10,000 mg/l	: Evaporation
Mid TDS, 1,000-10,000 mg/l	: R.O., EDR
Low TDS, -1,000 mg/l	: IX and CIX

- Nature of Contaminants:

High $CaSO_4$	: R.O. Slurry Seeded
Non-Scaling	: EDR/R.O.
Fe, Mn	: EDR/R.O. with Pretreatment
NaCl, LT 2,000 mg/l	: Sirotherm IX
U_3O_8 Specific Recovery	: CIX

- Disposal of Concentrates:

Deep Well Disposal
Ocean Discharge ($CaSO_4$, H_2SO_4, NaCl)
Evaporation Plants
Evaporation Ponds

DISPOSAL OF CONCENTRATES

In most cases, there is a point of diminishing return in the use of IX, R.O., and EDR as concentration of feedwater increases. These processes yield concentrates containing salts removed from the desalinated water and, as the volume of concentrate diminishes, its salt

concentration increases correspondingly. Eventually, it must be bled, and the cost of disposal of this concentrate must be included in an economic evaluation of the process.

Where the plant is located at the ocean, for example for seawater desalination, the concentrate can be discharged back to where it came from. If used for mine-mill related effluent treatment, ocean discharge would depend on the nature of the concentrate composition and the marine environment protection laws in effect but is seldom possible due to location.

Where low-cost land is available and the operation is located in net evaporation climates, evaporation ponds are most likely to be the more economical solution, especially where naturally impermeable formations exist on the surface which can be used in impoundment construction.

Where water is valuable and land is not available, evaporation to dryness in a plant is probably going to be attractive, especially if waste heat from a power plant is available or if a market can be found for the salt product.

At the Rustenburg Refinery, an acid metallurgical processing solution is treated with NaOH, and the Na_2SO_4 is recovered from wastewater after a lime-soda softening step using a Swenson evaporator. The Na_2SO_4 is sold to the fertilizer industry.

On the other hand, at mines such as the Beisa Mine, which is part of the GENCOR LTD. GROUP, minewater in large quantities containing 2,000 ppm NaCl is generated by mine dewatering. It is more economical to simply evaporate it from large shallow ponds. Where ponds have to be lined, where water is expensive or where there is net precipitation, the desalination/injection or desalination/concentrate evaporation alternative may prove most economical.

Selection of waste water treatment/disposal must be based on site-specific requirements and conditions.

R.O., evaporation, and ion exchange are discussed in greater detail in the chapters that follow to provide some insight into suppliers, existing installations, and sources of expertise. This is a highly competitive market, and some vendors may be led into making promises beyond their capabilities due to their general inexperience with mine-mill effluents.

A final word of caution is in order. Desalination processes are expensive in terms of capital and operating costs and somewhat more complex, more sensitive, and less familiar than most metallurgical processes. Solving one problem may introduce another, e.g., disposal of concentrates. Unless it really cannot be avoided, mining and mineral processing operations are best advised not to consider desalination processes.

As a starting point in the investigation of deep-well disposal of concentrates, the following person may be able to provide useful leads as to cost, sources of technology, and regulations in the U.S.A.:

ERLE C. DONALDSON
Research Chemist
Basic Production Research
U. S. Dept. of the Interior
Bureau of Mines
Post Office Box 1398
Bartlesville, OK 74003

Mr. Donaldson has undertaken surveys of disposal wells used by chemical industries in the U.S.A. and has described two disposal systems that may be of particular interest to the mining industry which were studied over a ten-year period by the Bureau of Mines.

Various cementing processes have been developed for the permanent safe disposal of precipitated solids. Amongst these systems are:

INTRODUCTION

Precipitation processes were discussed in the preceding chapter which pointed out that precipitation is the most commonly used process for the removal of contaminants from water.

Precipitation processes are discussed time and again in the following chapters on the removal of contaminants in which it is referred to specifically, contaminant by contaminant. Chapter 25 on Removal of Contaminants in particular contains much detailed discussion on various precipitation processes.

Here, it remains to draw attention to some of the innovative process ideas and equipment sources available. Since so much is said on this subject in later chapters, this chapter is designed to be no more than a summary overview of important features.

PRINCIPLES

The principles of chemical precipitation are discussed in all classical chemistry texts. Solubility of chemical species in water is governed by the solubility product Ksp which,

in turn is a function of temperature. Classical chemistry is not very good at quantifying phenomena such as supersaturation or co-precipitation effects. Consequently classical chemistry, while useful in providing a guide as to what one might expect to happen in a solution, does not compare with empirical results of what actually happens in practice, especially when dealing with complex solutions.

Porbauix diagrams represent a major step forward in explaining the stability in solution or solid form (precipitate) of a whole variety of species. These do not take into account the effects of the presence of complexing agents or other sequestering agents. In addition, so much also seems to depend on the nature of the surfaces to which a solution of salts is exposed as to whether they will be precipitated or not. In terms of adopting a systems approach to selection of precipitation reagents and conditions, it is important to think not only in terms of the solubilities that can be reached, but also to determine the degree to which suspended precipitates can be removed from the solution, the type of equipment required for this, and the cost thereof, as well as disposal of the precipitate.

An excellent example of this is the mammoth study undertaken by the Calgon Corp. to assemble empirical data on scaling and corrosion in power plants as a function of solution chemistry. This has resulted in a computerized databank on empirical and fundamental reaction data that is believed to have cost $7-8 million to assemble overy many years to accurately predict the solution chemistries and stabilities under various conditions as well as to predict the correct dose of scale inhibiting or anti-corrosion chemicals. This is known as their Calgard program.

RANDOL believes that for prediction of solution stabilities in metallurgical processes, the same type of empirical approach would be required--build a quantitative base for reliable salt balance modelling in integrated processes. However, such an empirical databank does not exist, nor is it likely because the cost would be even higher than it was for the Calgard system due to the more complex nature and variety of metallurgical processing plants. Information on the Calgard program is available from:

CALGON CORPORATION
Post Office Box 1346
Pittsburgh, PA 15230

Dr. Frank Daniher

APPLICABILITY

Precipitation is applicable as a means of removing contaminants from solution when:

1. The contaminant can be removed to satisfactory levels for the solution to be recycled or discharged.

2. The precipitate can be economically separated from the solution.

3. The reagent used in the precipitation process does not make the solution more toxic than the species that was precipitated.

4. The precipitate can be disposed of safely.

5. If more than one species needs to be removed from solution, a process that simultaneously removes all of them will be most applicable.

OXIDATION OF IRON

Ferric hydroxide precipitates at around pH 3.5 whereas, ferrous hydroxide is more soluble and precipitates at a higher pH. For more effective removal of iron from solution, it is best ot oxidize it to ferric iron. The normal procedure for this is by air oxidation. The rate at which ferrous ions oxidize in air to ferric is very pH dependent and varies from many hours at low pH, say 2, to minutes at high pH values. Consequently, it is normal practice to add lime before aeration of acid solutions containing ferrous ions.

EQUILIBRATION

When water is in contact with the atmosphere, it adsorbs CO_2 from the atmosphere. At low pH values, this CO_2 is present in solution as H_2CO_3, carbonic acid. Below pH 7.2, it is present as HCO_3^- bicarbonate, and above pH 7.2, it is present in solution as carbonate ions $CO_3^=$.

A solution is in equilibrium when it has adsorbed CO_2 from the atmosphere to an equilibrium level. Since some carbonates, e.g., $CaCO_3$, are a lot less soluble than the hydroxides, e.g., $Ca(OH)_2$ of the same metal or the bicarbonates, e.g., $Ca(HCO_3)_2$, solutions in an acid medium will adsorb CO_2 until the solution is saturated. If the pH were to be increased to over pH 7.2, the bicarbonate ions convert to carbonate ions, and insoluble carbonate precipitates may settle out, thereby consuming CO_2 from the solution. Sometimes these processes take a long time, and non-equilibrium conditions may exist.

LIME ADDITION PROCESSES

Lime may be added in several ways for pH adjustment or to precipitate contaminants:

- Direct addition of unslaked lime to a tank or effluent stream as described at INCO, Copper Cliff, in Appendix I can and does achieve satisfactory contaminant removal to fulfill the needs of some operations.

- Slaked lime makeup and addition as a solution.

- Addition of dry slaked lime as a powder as described at Waite-Amulet in Appendix I.

- Lime slakers, lime solution dosing equipment is standard and available through most mine supply houses. The system installed at Noranda Waite-Amulet is very practical and is designed to be completely automated with no operator on site.

Lime addition makes it possible to reach pH values in excess of pH 12.

The lime feeder and slaking system installed at the Mount Emmons water treatment plant uses a slaker that feeds lime from a silo at 1,000 lb./hour to make a 6-8% slaked lime slurry. This system operates reliably and was supplied by:

WALLACE AND TIERNAN DIV.
Pennwalt Corporation
25 Main Street
Belleville, NJ 07109
(201) 759-8000

Slaked lime addition is automatically controlled by a pH meter and a solution level probe. There is always a backup probe on standby. The pH probe used was supplied by:

GREAT LAKES INSTRUMENTS, INC.
8855 North 55th Street
Milwaukee, WI 53223
(414) 355-3601

At the Copper Cliff water treatment plant of INCO Ltd., Sudbury, Ontario, 272,000 m^3/d of water is treated. A slaked lime slurry is pumped into the creek feeding the water treatment plant about 50 yards upstream of the plant inlet. The slaked lime slurry is generated on site from quicklime. A total of 4,000-5,000 tpa is consumed annually to adjust the solution to pH 10-10.5.

INCO has found that by moving the lime addition point upstream of the plant inlet, a significant improvement in reactor-clarifier performance and final effluent clarity resulted.

At Key Lake, a high acidic uranium raffinate mixed with large volumes of excess minewater is neutralized in their "bulk neutralization" plant which employs four flash mixer tanks in series which are inserted before each of four reactor tanks. The addition of lime in this way is effective at precipitating a sludge that can be densified to 20% solids

in a lamella settler and has also proven effective at precipitating arsenic. This system was designed and pilot tested for Key Lake Uranium by:

SHERRITT-GORDON MINES LTD.
Fort Saskatchewan, Alberta
Canada T8L 2P2
(403) 988-6911
Herb Veltman
D. Robert Weir
Roman Berzowsky

The manner in which lime is added in precipitation processes has a lot to do with the nature of the precipitate density and can also influence lime consumption as can be noted from the next paragraphs on HDS precipitation.

Where a lime slurry or solution is to be spray irrigated through nozzles in water treatment processes, then the type of lime used is significant as it should be free of silica particles that can clog the sprinklers.

LEVINS (1978) showed how dissolved salts in Alligator Rivers area acid leached uranium tailings solution are reduced as pH is increased by addition of lime.

THE HIGH DENSITY SLUDGE PROCESS (HDS)

The high density sludge process was first described by the Bethlehem Steel Corp. and has since been used and, in some cases, improved on by at least the following mining companies:

Rand Mines (Mining and Services) Ltd., Johannesburg
Cominco Ltd., Kimberly, B.C., and Trail, B.C.
Noranda Mines Ltd., Waite-Amulet and Several Locations
Bethlehem Steel Corp., Several Locations
Anglo American Corp., Kromdraai

Several of these installations are described in Appendix I trip reports, and the process is described in detail in Chapter 24 on acid mine drainage treatment. The paper by WATSON and TURNBULL (1983) overleaf describes the application of HDS at Cominco's Trail, B.C., metallurgical operation.

The main advantages of the HDS process are:

- Generation of high sludge densities that settle easily and are easily disposed of.
- More efficient lime utilization.
- Non-amphoteric precipitates.
- Clearer clarifier overflow.

The main feature of HDS is the recycling of underflow sludge which is premixed with lime before it is added back to the circuit.

There are several sources of up-to-date information on the latest applications and performance of HDS. These include:

WALTER J. KUIT
Cominco Ltd.

BETHLEHEM INTERNATIONAL
ENGINEERING CORP.
Bethlehem, PA 18016
(215) 694-2424
Stewart T. Herman

The Bethlehem International Engineering Corp. (BIEC) offers a commercial service to design HDS systems for specific applications as well as for sludge disposal. BIEC has recently patented improvements in HDS applications for base metals removal from water--for example, zinc precipitation, and another for manganese precipitation when iron is present at low levels. The Bethlehem Steel HDS plant at their Panther Valley Mines operation, Mauch Chunk, Pennsylvania, uses an innovative preaeration technique which reduces lime consumption cost effectively in an area where lime is inexpensive.

1982 ENVIRONMENTAL ENGINEERING DESIGN AWARD

Cominco Ltd is the winner of the second Environmental Engineering Design Award of the Association of Professional Engineers of BC. Cominco's Effluent Treatment Plant at the Trail Metallurgical Operation was judged the best design for 1982 and their submission is published here in full.

The Award was presented by APEBC President Ken Williams PEng to authors Roger Watson PEng and John Turnbull PEng at the West Kootenay Branch Meeting in Castlegar on March 24, 1983.

Seven other submissions were received from coal mines, pulp mills, engineering consultants, municipalities and government departments. Extracts from these submissions were prepared by Kelly Kline PEng of the Environment Committee and, with the authors' permission, are published in this issue.

1982 Environmental Engineering Design Award Winner

Cominco Ltd's Effluent Treatment Plant at its Trail, BC, Metallurgical Operation

R H Watson PEng, Manager
J D Turnbull PEng, Assistant Manager
Trail Modernization Project

INTRODUCTION. Cominco Ltd's huge metallurgical complex is located in Trail, British Columbia, a city with a population of 10,600 located in the Columbia River Valley in the West Kootenays, 18 km north of the Canada-US border. The lead-zinc production complex is the largest in the world with an annual capacity of over 400,000 tonnes combined lead and zinc. As a consequence of this installation, 30 tonnes of silver and over 325,000 tonnes of chemicals and fertilizers are produced annually. Gold, cadmium, bismuth, antimony, arsenic, and indium are also recovered as by-products.

John D Turnbull PEng, Assistant Manager, Roger H Watson PEng, Manager, Trail Modernization (centre), receive the APEBC 1982 Environmental Engineering Award from Ken Williams PEng

Trail Operations' Effluent Treatment Plant is part of the modernization and expansion program announced by Cominco in 1977. To the end of December 1982, Cominco has expended about $335-million. It is expected that the modernization program will cost in excess of $700 million when completed and that the internal and external aspects of environmental control will amount to approximately $200-million.

From its earliest days, Cominco has demonstrated a responsible corporate attitude towards the environment and has made concerted efforts to minimize the impact of its metallurgical operations on the environment. Its efforts with respect to environmental control date back to 1927 when it undertook steps to control sulphur dioxide and heavy metal particulate emissions from its smelting operation with the installation of a chamber plant to produce sulphuric acid from zinc roaster gas.

Cominco's efforts, which anticipated environmental legislation by several decades, have paid handsome environmental dividends over the years. The Columbia River at Trail has continued to be a favourite among local sportsmen whose fishing activities range from shoreline angling to trolling from boats. Fish caught above and below the Trail plants are of excellent quality and comply with Canadian and foreign standards for food as shown by studies carried out between June 1977 and October 1981. Studies concerning blood-lead levels, lung function and

general health of local residents have shown that Trail is a good place in which to live and bring up children.

NEW WASTE MANAGEMENT BRANCH REGULATIONS

Notwithstanding the fact that Columbia River water downstream from the Trail plants was well within drinking water standards for metal content, it was anticipated that new, discharge-related Waste Management Branch regulations would ultimately necessitate an effluent treatment plant. Consequently, Cominco Engineering prepared a feasibility proposal which outlined the process and plant design, project schedule and capital cost. Funds for the project were appropriated and the project team was mobilized in October, 1978.

On November 29, 1978, Cominco Ltd was issued Pollution Control Permit No PE-2753. The permit requires that the contaminant loadings in effluents discharged into the Columbia River from Trail metallurgical operations be reduced to meet specific maximum levels of contamination by January 1, 1983. The effluent treatment plant was to operate in conjunction with various metallurgical process improvements and other environmental projects to achieve the stringent quality objectives specified in this permit.

PROCESS TECHNOLOGY

The Trail Operations Effluent Treatment Plant uses the high density sludge (HDS) version of the basic lime precipitation process which was researched intensively by Cominco Ltd. Cominco's first application of this process was the $10 million Effluent Treatment Plant at its Kimberley Operations, officially opened in October 1979.

The HDS process recycles a substantial proportion of the clarifier underflow sludge. This material is blended with the lime slurry necessary for neutralization prior to mixing in the main reaction vessels. The pre-mix is an important feature of the process that modifies the physical characteristics of the sludge solids from a fluffy slime to an almost particulate texture.

In the course of pilot plant testing of Trail Operations effluent, Cominco Technical Research personnel simulated various upset conditions in order to be able to design a plant that would handle the combination of varying flow rates and effluent characteristics from various sewer systems of the complex metallurgical operation.

$9-MILLION TREATMENT PLANT

The $9-million Effluent Treatment Plant for Cominco's Trail lead-zinc operation is one of several environmental projects that ultimately will allow Cominco to meet the new Provincial environmental standards.

Because the plant is located next to a residential area, it was built with aesthetic considerations in mind. Extensive landscaping and an attractive exterior were features of the design.

The plant has a treatment capacity of 4500 litres of effluent process water per minute, but because of the incorporation of a large holding tank for incoming feed, the plant can handle emergency surges of up to 9000 litres per minute. Flows from various sewer systems from 20 separate areas at the Trail metallurgical complex are treated in the plant.

The collection system connecting the various industrial sewers to the treatment plant involved the construction of an underground gravity flow piping system. Thirteen effluent streams from the zinc operations are collected and drained to the treatment plant. The major flow from the zinc plants, roaster off-gas cooling water, is stripped to SO_2 prior to being sent to the treatment plant, thereby minimizing sludge production. Effluent streams from the lead smelter are first collected in a thickener where they are neutralized to pH 6.5. Thickener overflow is then pumped to the plant for treatment.

Effluent streams from the lead smelter and zinc operations are received in a 23-metre diameter mild steel storage tank lined with neoprene rubber for corrosion resistance. The tank is aerated to keep the solids in suspension. Tank exhaust air is water scrubbed and the scrubber effluent water is sent to the reaction tank for neutralization. The storage tank provides a 15-hour surge capacity for blending of the varied feed streams, dilution of acid spills and allows for short-term plant maintenance shutdowns.

From the storage tank, a controlled flow of the combined effluent is pumped to the first of two 106,000-litre fibreglass reinforced plastic (FRP) reaction tanks in series, for neutralization with lime to pH 10. Both reaction tanks are baffled and agitated to ensure proper mixing.

Pulverized quicklime is received pneumatically in a 150-tonne bin from a bulk delivery truck. The bin is provided with a vibrating bin discharger bottom that ensures a continuous flow of material and prevents bridging and rat-holing in the bin. Air is exhausted via a pulse jet bag filter mounted on top of the silo.

A variable speed screw feeder meters the quicklime into a paste-type lime slaker where it is hydrated. The lime slaker is essentially a mild-steel conveyor trough in which lime and water are mixed with rotating paddles. Hydrated lime is stored as a 10% lime slurry in a 106,000-litre FRP tank. The tank has four internal baffles and is agitated to maintain a homogeneous mixture. Quicklime is drawn off the tank by centrifugal pumps and pumped to a 4000-litre capacity opened top FRP tank where it is pre-mixed with recycled clarifier underflow sludge.

The combined slurry overflows the premix tank and is mixed with the effluent in the reaction vessels where neutralization and precipitation is accomplished. The pH in the reaction tanks controls the lime slurry flow rate to the premix tank.

Neutralized effluent slurry from the reaction tanks is mixed with a flocculant in a 3500-litre mix tank which overflows to a clarifier for liquid-solid separation. The flocculant, an organic polymer, is added to improve the settling characteristics of the fine precipitate. This promotes rapid settling of the sludge particles in the clarifier producing a clear effluent overflow for discharge to the Columbia River. This overflow is continuously monitored for turbidity and pH.

The clarifier is a 25-metre diameter by 3-metre deep concrete tank with a slow moving rake mechanism that draws the settled solids to the bottom center cone while allowing incoming solids to settle undisturbed. Settled sludge is removed from the clarifier at about 25% solids. A major portion of this sludge is recycled and mixed with the lime slurry used for neutralization. The balance is pumped intermittently, depending on the sludge production rate, to the Lead Sinter Plant. In the Sinter Plant, the sludge is combined with a reclaimed lead slurry stream, dewatered on a drum filter and mixed with zinc leaching plant residue slurry for treatment and recovery of the metal values. The filtrate joins other Sinter Plant effluent streams for return to the Effluent Treatment Plant.

A simplified flow diagram of the plant is shown in Figure 1.

FIGURE

Detail of Cominco's Effluent Treatment Plant at its Trail Operations. At the left is the surge tank, in the background is the main process building and to the right the clarifier.

PLANT PERFORMANCE

Plant commissioning proceeded in an orderly manner with no major problems and the plant was started on June 8, 1981. The startup went smoothly and the maximum design rate was achieved after only three days of operation. Design limits on the discharge turbidity and pH were met from the very first day.

Since startup the new plant has performed as expected.

Recovery of zinc, lead and cadmium from the processed streams has been good:

	% Recovered
Zinc	98.9
Lead	99.5
Cadmium	97.5
Suspended Solids	92.9

The Effluent Treatment Plant has contributed to an overall reduction in heavy metals in the effluent leaving the Trail plants. Columbia River water quality data are shown in Table I.

Operating costs have averaged $50,000 per month with lime cost contributing 40% of the total. The metals recovered in the plant, after subsequent reprocessing costs and other associated savings, serve to offset the operating costs to a large extent. Typical of most environmental control projects, there is no return on the capital invested.

An unexpected benefit of the treatment plant is that it has acted as a "policeman" to the metallurgical operation. Any short term process upsets that previously resulted in unrecognized discharges to the river are now readily detected, their origin traced and corrective action taken. During such upsets, the Effluent Treatment Plant, with its conservative design and surge capacity, acts as an effective buffer to prevent the discharge of metallic effluents to the Columbia Rover.

ENGINEERING AND CONSTRUCTION

The Effluent Treatment Plant was designed to meet the strict requirements of the BC Ministry of the Environment. The process and design specifications which served as the basis for detailed design (see Table II) were established by Cominco Technical Research and the Trail Modernization Group. Because of the environmental focus of the plant, extreme attention was paid to minimizing periods of plant downtime. As a consequence of this philosophy, features such as 100% surge capacity, double piping in certain areas, and installed standby pumps were included in the design criteria.

Project management, project services, overall design responsibility and construction were provided by Cominco Engineering. Hatch Associates Ltd of Toronto were responsible for the detailed design work while process technical services were provided by Cominco Technical Research.

The technology, design, construction and operating expertise developed as a result of this project is now being made available to third parties through Cominco Engineering Services Ltd (CESL), a wholly-owned subsidiary of Cominco Ltd.

ACKNOWLEDGEMENTS. Successful implementation of a project of this nature required the broad spectrum of technology, know-how and experience of a large number of professional engineers, technicians, technologists and specialists from within the Cominco organization. Particular acknowledgement is accorded the following key members of the project team:
P Huszti, Operations Representative
W J Kuit, Assistant Manager, Environmental Control

Cadmium, dissolved	<0.005	<0.005	<0.01

Average flow = 2,380 m^3/sec

Table II. Effluent Treatment Plant Data
- Capital cost: $9.0-million
- Completion: June, 1981
- Effluents treated: Contaminated streams from 20 areas in Lead and Zinc Operations
- Effluent collection capacity: 4500 LPM normal; 9000 LPM surge capacity
- Surge tank: 23 metre diameter; 3.6-million litres capacity
- Lime silo: 150 tonnes quicklime
- Lime slaking capacity: 1.8 tonnes per hour
- Process
  - Feed: 4500 LPM normal; 6000 LPM maximum
  - Reactors: two in series, 20 minutes retention time each
  - Lime neutralizes acid and precipitates metal present (usage 11 tpd).
  - Flocculant: use 6 kg/d; added to assist solids settling in clarifier
- Clarifier: 25 metre diameter; 1.7-million litres capacity
- Products: clean water to river; 20 tonnes of sludge per day to Lead Smelter
- Labour: 1 operator per shift
- Operating cost: $50,000 per month

The Effluent Treatment Plant at Cominco's Trail Operations. At the left is the surge tank, to its right the main process building with a tower housing the lime bin and in the foreground the clarifier from which the overflow reports to the Columbia River and the underflow back to the metallurgical plants for the recovery of metal values.

MAGNESIUM CARBONATE TREATMENT PROCESS

BLACK and THOMPSON (1974) describe plant-scale studies of the magnesium carbonate water treatment process in which three primary water treatment chemicals, magnesium, carbon dioxide, and lime are recycled within the process. This process has been installed for municipal water treatment at Montgomery, Alabama, and at Melbourne, Ohio, and it offers significant savings in land disposal requirements and reagents.

The increased floc density of the magnesium process allows higher clarifier loading rates. At the Melbourne, Ohio, plant loading rates were doubled without deterioration in water quality of clarifier effluent.

The levels of several base and heavy metals in water product was significantly lower when the magnesium carbonate process was used compared with conventional lime precipitation tests on the same solutions. The report by BLACK and THOMPSON (1974) on magnesium carbonate water treatment is available from the National Technical Information Service, Springfield, VA, 22151.

The consultants that evaluated this process were:

BLACK, CROW and EIDSNESS, INC.
777 South Lawrence Street
Mongomery, AL
A. P. Black

The address of the Montgomery magnesium carbonate water treatment plant is:

MONTGOMERY WATER AND SANITARY
SEWER BOARD
Post Office Box 1631
Montgomery, Alabama 36102

No references have been found to magnesium carbonate use in minewater treatment. This would be more applicable perhaps for very large installations, large enough to justify recycling plants to recover lime, $MgCO_3$, and CO_2, or where low-cost sources of $MgCO_3$ and CO_2 are available.

MAGNESIUM OXIDE PROCESS

SHILLER and KHALAFALLA (1981) patented a process whereby a substantial excess of essentially dry, powdered magnesium oxide is added directly to feedwater. The resulting precipitate is found to settle very readily to a small volume. The precipitate is not readily redispersed or redissolved. The product water is claimed to be recoverable by simple decantation avoiding the need for filtration, and metals such as Cd, Cr, Cu, Zn, Fe, Mn, Ni, and Pb are effectively removed. An essential difference in the way the

reagent is added is that MgO powder is added dry to the water being treated rather than as a slurry or solution.

The patent application US 325269 is available from the National Technical Information Service, Springfield, VA, 22151, but contains very little information. Their document number is PAT-APPL-6-325-269. The authors are employed by the U.S. Dept. of the Interior; they are Joseph E. Schiller and Sanaa E. Khalafalla, but Randol was unable to find out where.

LIMESTONE ADDITION PROCESSES

Limestone addition can bring pH of solutions up to around pH 6.7 or so, but not high enough to precipitate most base metals quantitatively.

The biggest problem with limestone addition is that iron and other hydroxides precipitate on the surface of the limestone rendering it passive. Several ways around this have been devised:

1. Fine grinding of limestone before addition as a slurry as described at the Onaping operations of Falconbridge in Appendix I and by a Bureau of Mines ROI inserted in Chapter 24 on Acid Mine Drainage Treatment.

2. The use of granular limestone in tumblers driven by a waterwheel powered by the effluent stream itself as demonstrated in Pennsylvania by the state and descirbed in the chapter on acid mine drainage treatment.

3. At Greenside Colliery, South Africa, Gold Fields Mining in conjunction with a supplier, Water Care (Pty) Ltd., attempted to use granular limestone in a "hog trough" shaped contactor fitted with air hoses for periodic attritioning to remove coatings. This proved unsuccessful as a means of neutralizing acid mine drainage. Details and contacts are also provided in Chapter 24 on Acid Mine Drainage Treatment.

NaOH ADDITION

NaOH addition for metal precipitation in effluents works both cleanly and rapidly. The main disadvantage is the extra cost of NaOH which is usually much more expensive than lime.

NaOH addition is, however, convenient and cost effective for small installations where it does not pay to install and operate a lime slaking facility. One such example at the

Onaping minewater neutralization plant is described in the trip report on Onaping in Appendix I. An important consideration is the high freezing point of NaOH solutions, which in all other respects are very convenient to use.

In Chapter 24 on acid mine drainage treatment, a system employing a jet pump and static mixer for instantaineous flash precipitation of metals is described. This system, developed by the Bureau of Mines, Pittsburgh, is portable and requires a minimum capital investment. More information on this innovative system can be obtained from:

BUREAU OF MINES
U.S. Dept. of the Interior
Post Office Box 18070
Pittsburgh, PA 15236
(412) 675-6422
Terry Ackman

A most innovative new device for flash precipitation of metals using this type of equipment is the flash mixing jet pump for mixing air, NaOH solution, and the feed solution to be treated, as described in Chapter on acid mine drainage treatment. More information on this versatile item of equipment with several different process uses could be obtained from:

BARRETT HAENTJINS CO.
225 North Cedar Street
Hazelton, PA 18201
(717) 455-7711
John R. Ackerman

MINIMUM CONCENTRATIONS ACHIEVABLE BY LIME PRECIPITATION

Metal	Minimum Conc. (mg/l)
Iron	5×10^{1}
Zinc	3×10^{2}
Cadmium	3×10^{0}
Nickel	7×10^{-1}
Copper	2×10^{-2}
Lead	2×10^{0}
Mercury	6×10^{-4}
Silver	2×10^{-1}
Chromium	1×10^{-3}

The above data was taken from the Permutit Co. Technical Bulletin No. 6, Vol. XIII, Code 4413 2002, which references the source as Lange's Handbooke, 11th Edition. More reliable data appears to be that presented in the following graph of metal concentrations at various pH values published by the EPA.

Precipitation of metal salts versus pH

CHEMICAL INTERFERENCE WITH PRECIPITATION

The above indications of minimum concentrations refer to levels in deionized water for pure chemicals. In real life, complexing agents tend to keep higher levels of most metals in solution than the idealized levels. Other factors could reduce the solubility below the levels indicated above; for example, lead would likely be precipitated well below the 2.0 mg/l indicated in the table at alkaline pH due to carbonate levels that occur naturally in water.

HDS and cross-flow microfiltration processes introduce co-precipitation and surface phenomena that reduce metal levels below their theoretical solubilities.

Common complexing agents which would interfere with hydroxide precipitation of metals are:

Humic Acids (Decaying Plant Matter)
Fulvic Acids (Decaying Animal Matter)
Cyanide Ions
Ammonia Ions
EDTA
Solvent Extraction Reagents - Colloidal Suspension
Ion Exchange Resin Fragments
Activated Carbon Particles in Suspension

Frequently, even if metals have been precipitated to their solubility limits, samples of solution, even after settling or filtration, may show higher levels when analyzed. This is

often due to suspension of colloidal particles of precipitate which report in the sample analyzed.

It is wellknown that sequestering agents can be added to $CaSO_4$ and $CaCO_3$ solutions which increase the solubility of these compounds in water by a factor of 300%. Is it not possible that the same type of effects could influence solubilities of other metals, even those that are more sparingly soluble. It is also known that commonly occurring anions such as carbonate, sulfides, and thiosalts can act as complexing agents. For example, carbonate ions complex uranium and also calcium ions. In situ leach leaching solutions are injected underground under pressure, and CO_2 is injected as a lixiviant. When pressure is released and CO_2 allowed to escape, $CaCO_3$ precipitates. H_2S under pressure may dissolve base metals and keep them in solution. At Steamboat Springs, just outside Reno, Nevada, base metals can be observed to precipitate from a hotsprings as sulfur gases exsolve. Of course, temperature effects probably also pay a roll.

H_2S POLISHING OF SOLUTIONS

Sulfides of many metals are much less soluble than the hydroxides. However, a common objection raised against sulfide precipitation is that the sulfide precipitates themselves may potentially become "hazardous wastes" as defined in U.S. regulations. The concern is that if sulfide precipitates are oxidized at some time in the future, the metals will resolubilize. What is unclear is what is so much different about redissolution of metals from a sulfide or from a hydroxide precipitate as to make one preferable to the other?

However, another alternative is to use sulfide addition as a polishing means after as much as possible of the metals have been precipitated using lime or other precipitants. The sulfide may be added in one of several forms including Na_2S, NaHS, or freshly prepared FeS.

Sulfide precipitation and its performance in several cases is discussed in the chapter on acid mine drainage treatment and on the removal of individual cations. A highly innovative use of sulfide precipitation in which sulfide is introduced in the form of FeS was invented by the Permutit Company for application in the treatment of plating wastes.

Information on the patented Permutit process and equipment for their SULFEX Process is provided in Chapter 25 or can be requested from:

THE PERMUTIT CO., INC.

Telex: 134-488
Robert V. Nagiel
Product Manager

It is believed that the General Electric Laboratories have developed a process employing CaS or a mixture of lime and Na_2S for solution polishing, but they failed to respond to enquiries.

In the mining and mineral processing industry, no examples were found where sulfide precipitation is being used in North America for effluent treatment or polishing. During the course of this investigation, the American Mining Congress was suing the EPA on behalf of the mining industry to have them retract the requirement for the use of sulfide precipitation under the BAT regulations for effluents from base metal refineries.

An EPA summary report described the use of sulfide precipitation of heavy metals from a solution containing arsenic, copper, zinc, and fluoride at one of Boliden's smelters in Sweden is included in the section on arsenic removal and on copper removal in a later chapter.

Possibly because of the litigation in progress through 1984 between the EPA and the mining industry, this subject was considered sub-judice.

One metallurgical plant in the midwest was precipitating base metals by sulfide addition before using lime to neutralize a waste acid stream. Before sulfide precipitation was applied, the lime precipitated-gypsum did not pass the EP leach test. However, after inserting the sulfide precipitation step, the gypsum precipitated was disposable in a sanitary landfill. The mining company involved asked not to be identified.

LIME-SULFIDE PRECIPITATION

MIKHNEV, et al. (1978) describe the use of a sulfide solution in $Ca(OH)_2$ to precipitate heavy metals from metallurgical plant effluent. The Cu, Ni, and Fe were precipitated at pH 5.2, 7, and 7-9 respectively. The degree of removal depended on pH and the composition and dosage of the added $Ca(OH)_2$- $S^=$ solution, and to a very limited extent, on temperature (20-80°C). The treatment at final pH 7.5-8 decreased the metal concentrations as follows:

	Inflow	Outflow
Cu (mg/l)	70	0.1
Ni (mg/l)	80	0.01
Fe (mg/l)	10	0.01

The precipitate contained about 12% Cu, 12% Ni, and 20% CaO as CuS, NiS, and $CaSO_4$.

Importantly, the use of $Ca(OH)_2$- $S^=$ solution increased the clarification rate by 50-100%.

USE OF PLANTS TO POLISH EFFLUENTS

In most mining districts where there is adequate precipitation for there to be yearround or even seasonal water flow, marshes are commonly observed in shallow drainage areas.

These naturally occurring marsh-type environments have been observed to "polish" discharged mine and millwater effluents. This phenomenon is discussed in some detail in Chapter 25.

Examples of systems where these polishing phenomena have been observed include AMAX Inc.'s Buick Mine and Mill where a meander system containing macro algae growth polishes metals and flotation reagent organics from the effluent. St. Joe Minerals' Edwards mill tailings final effluent at Balmat, New York, is polished as it traverses a natural marsh. A hugh swamp at Falconbridge Nickel Mines operations outside Sudbury, Ontario, is another example of a marsh containing plants and algae that play a role in water cleanup.

The mechanism for water cleanup may be through metabolic metal uptake by plants and/or algae. Also, however, as the biomass dies back and forms a carbon-rich anaerobic zone at the bottom of the marsh, bacterial action is likely to release enough H_2S (marsh gas) to precipitate metals from solution. Sulfates in the water provide the source of sulfur which is reduced to H_2S or to soluble sulfides or even FeS which would provide a reservoir of sulfide for base metal precipitation. The metal sulfides sink to the sediments on the marsh bed.

Marsh environments serve to host aquatic plants, algae such as Chara, and, of course, bacteria. In developing and engineering such systems to gain optimum results, it is the whole marsh ecosystem that must be examined, not just parts of it. This means that a multi-disciplined R&D effort is needed, not isolated laboratory studies on plants, algae, and bacteria separately.

The huge surface area presented by plants and algae in natural marshes has been observed to polish suspended solids from effluents. It is worth investigating further to what extent such marshes could be engineered to be even more effective. In Ontario, marsh plants and algae are prolific around mine-mill areas in summer but die back during winter. In South Africa on the Witwatersrand, similar marshes are observed wherever water is released, i.e., downstream from minewater discharges, tailings pond runoff release areas, natural springs, etc. The water in the marsh environments closest to tailings dumps is usually red-brown in color, either due to colloidal $Fe(OH)_3$ suspensions or organic marsh-derived compounds. Further downstream after the water has passed through a larger area of marsh, prolific aquatic birdlife is supported in these marshes indicating that the aquatic environment is suitable for numerous aquatic invertebrates as well. Much more work is needed to try and make use of these systems.

The use of plants is largely still in the early stage of investigation. In Canada, the Ontario Ministry of the Environment undertook an interesting experiment to engineer a marsh for the treatment of raw sewage. Also, Dr. Margaret Kalem of Boogum Research is involved in the study of volunteer species in tailings ponds of uranium mills in the hope of finding species that thrive in that environment.

DENSIFICATION AND DISPOSAL OF PRECIPATED SLUDGES

Disposal of precipitate sludges is almost as important as the technology used to form the sludges in the first place. The sludges contain the unwanted contaminants that were removed from water, only in a very much more concentrated form.

Several disposal techniques are employed:

- At Noranda Mattabi Division, a copper-lead-zinc mine, zinc precipitate sludges were formerly added to their zinc concentrate for shipment to the refinery where incremental zinc metal values would be recovered from them.

- At most copper-lead-zinc mine/mill complexes, precipitate sludges are returned to the tailings pond. These sludges are amphoteric for the most part, i.e., they go back into solution if the pH is allowed to become acid, and it is conceivable that this could well happen in tailings ponds containing sulfide minerals. At INCO's Copper Cliff mine and smelter complex, precipitate from the lime-settle-filter water treatment plant is pumped back to the tailings pond. It is true that the amount of metals in the tailings material is usually greater than the amount that is pumped back as a sludge, but is it all as amphoteric as the sludge?

- The (HDS) high density sludge process yields precipitates with up to 50% solids. These sludges, when mixed with cement or certain types of fly ash and lime set up in a pozzolonic reaction which meets the EP toxicity tests and are, therefore, suitable for disposal in sanitary landfills. The Bethlehem Steel Corp. has demonstrated the equipment and process for the formation of pozzolans for safe sludge disposal:

BETHLEHEM INTERNATIONAL
ENGINEERING CORP.
Bethlehem, PA 18016
(215) 694-2424
S. T. Herman

- AMAX, Inc., at the Mount Emmons water treatment plant, takes a 2-3% solids precipitate sludge and dewaters it on a Parkson belt press before mixing the dewatered sludge at 12% H_2O with cement in a special mixing device which is cured

and then disposed of elsewhere. After dewatering and mixing with cement, the precipitate passes the EP leach test.

- Where amenable, one of the most innovative ways of disposing of precipitated metal sludges is to dispose of them with tailings that are disposed of using the "semi-dry" or "subaerial" tailings disposal technique. These can have such low permeabilities that the mixing of precipitated metal values into the tailings should effectively encapsulate them preventing metals from leaching out again. It also prevents CO_2 from the air from reaching the precipitates which could become unstable were they to spend years in contact with water and atmospheric CO_2, as described in the case of barium arsenate precipitates, for example. However, "semi-dry" tailings disposal works best in a drier climate and does not make very low impermeability tailings from all types of material. More research is needed to investigate and optimize this aspect.

The stability of sulfide precipitates after these are disposed of is raised as a questionmark. Sulfide precipitates seem to be a lot more stable than hydroxides, and it is curious that industry should be able to live with hydroxide/lime precipitate disposal more easily than with sulfide precipitate disposal. One possible reason is that lime precipitates can be disposed of with an excess of lime which would prevent their acidification and redissolution. Excess sulfide addition to precipitate sludges is not recommended--it seems that acidification of sulfide precipitates may result in the generation of H_2S, a gas more toxic than HCN. However, possibly sulfide sludges could be mixed with lime before disposal to inhibit acidification thereof. Ideally, sulfide sludges should be encapsulated in impermeable "sub-aerial" tailings or mixed with an encapsulating pozzolon. Sponsors are reminded that the Black Sea is named for the color of the sediments found on its shores and on the lake bottom which are black in color because of FeS precipitates that have settled there over millions of years by bacterial action on sulfates. Nature's sulfide precipitate disposal seems to be stable enough.

Reverse osmosis is an emerging technology for water recovery from saline and brackish water. Numerous, very large reverse osmosis plants are in operation, particularly for potable water recovery from seawater, and a huge number of small units are installed for production of germ-free water, boiler feedwater, and potable water, the latter on board trawlers and naval vessels. A huge effort has gone into membrane development and into the development of improved R.O. modules as well as the ancillary equipment required for R.O. systems (e.g., pumps, valves, controlers, etc.). This effort promises to reduce the cost of installation and to expand the applicability of reverse osmosis. Already, several R.O. systems have been installed in mine-mill environments for boiler feedwater treatment, effluent treatment (one unit at Matthey Rustenburg), and tiny units to supply battery water.

Even though R.O. modules, pumps, valves, etc. may appear simple to hook up and operate, these systems are frought with operating problems. LEGER (1983) described some of the pitfalls and problems experienced by some South African operators who treat Johannesburg tapwater. Most problems could be ascribed to inadequate recordkeeping and lack of knowledge about the sensitivities of R.O. In order for conventional R.O. processes to work reliably, pretreatment of the water is often needed. This would be particularly likely in the treatment of typical mine and mill effluents which contain iron, manganese, Ca^{++}, $SO_4^{=}$, $CO_3^{=}$, and colloidal organic species. WILMOTH (1973) and SASTRI & ASHBROOK (1976) reviewed applications of R.O. to acid mine drainage treatment, but their testwork would have not been able to take into account more recent R.O. improvements.

In order to be used as drinking water, the permeate from R.O. units, as with most desalting processes, may well require post treatment, but this is no major problem.

SOURCES OF INFORMATION ON R.O.

There are several excellent reviews on reverse osmosis including: SRI (1983), SCHUTTE (1983), and BURNS and ROE (1979).

Equipment vendors can supply a wealth of information, but their guidance generally includes a recommendation of their own products.

There are very few companies with experience in mining and metallugical operations and their water needs that also have experience with desalination operations. The closest that one can come would appear to be the service and engineering companies:

An important aspect about R.O. installations in mine-mill operations is where in the overall system to insert the desalination process. More important even, is the ability and motivation to review the overall water and salt balances of the complex to determine whether installation of a desalination plant can somehow be avoided by creative water management.

PRINCIPLES OF R.O.

There are several good basic texts on reverse osmosis technology. Unfortunately, these are written by academicians who appear more interested in the science of membranes than in their practical application, and their treatises rapidly become complicated and deeply involved with mathematical modelling of membrane transport phenomena which would be of little real interest to a mine or mill operator faced with the need to select an appropriate process for a water treatment problem. One reference book is by KING (1971).

Burns and Roe Industrial Services Corporation, Paramus, New Jersey, prepared a comprehensive document for the U.S. Dept. of the Interior, Office of Water Research and Technology, titled, "Reverse Osmosis Technical Manual," Work Order 4803-01, Contract No. 14-34-0001-8530, July 31, 1979, which provides a very comprehensive description of the reverse osmosis process. Possibly, this document is available from the National Technical Information Service, Springfield, VA, 22151.

In the reverse osmosis process, water flows selectively out of a concentrated salt solution and diffuses through a polymeric membrane and into a solution of low salt concentration. The natural process of osmosis would cause the water to flow in the opposite direction until a pressure imbalance equal to the differential osmotic pressure is built up. The osmotic pressure is proportional to the solute activity and, hence, is approximately proportional to the salt concentration. For natural seawater, the osmotic pressure is about 25 atm. This means that in the absence of other forces, water would tend to flow from pure water into seawater across a membrane permeable only to water--until a static head of 25 atm or 848 ft. of water was built up on the seawater side. At this point, this system would be at equilibrium. If the pressure difference across the membrane were less than the osmotic pressure, water would enter the seawater solution by osmosis but, when the pressure difference across the membrane is greater than the osmotic pressure, water will flow from the seawater solution into pure water side by reverse osmosis. In order for the water passing through the membrane to be salt free in a reverse osmosis process, it is necessary that the membrane be permeable to water but relatively impermeable to salt, since the salt would pass through the membrane with the water if the membrane were salt permeable, i.e., the membrane needs to exhibit good salt-rejection properties.

Reverse osmosis is distinguished from ultrafiltration and dialysis which are also rate-governed separation processes employing thin polymeric membranes. In rate-governed separation processes, mass transfer limitations in the fluid phase on either side of the separation barrier can reduce both the rate of product water transport across the membrane and the separation factor provided by the device.

The diagram below gives a schematic of the mass transfer processes occurring during reverse osmosis. Water passes through the membrane under impetus of the pressure drop

across the membrane (in excess of the osmotic pressure difference corresponding to the drop in salt concentration across the membrane).

Mass transfer processes occurring during reverse osmosis of salt water.

$$F_w = K\ (\Delta P - \Delta\pi) \qquad \text{---1.}$$

Similarly, the salt flux through a membrane is given by the equation:

$$F_s = k\ (C_b - C_p) \qquad \text{---2.}$$

where:

F_w, Fs	=	The water and salt fluxes across the membrane.
ΔP	=	The drop in total pressure across the membrane.
$\Delta\pi$	=	The drop in osmotic pressure across the membrane.
C_b, C_p	=	Salt concentration on the two sides of the membrane.
K, k	=	Empirical constants which depend on the membrane structure and the nature of the salt.

Water coming toward the membrane on the salt water side conveys dissolved salt with it; however, the salt cannot diffuse through the membrane at the rate the water does. As a result, there is an accumulation of salt at the membrane surface. The salt can be removed from the membrane surface only by diffusion back into the bulk salt water. The

FIGURE 6.3 Permeator assembly for hollow fine fiber membranes. (USAID 1980)

salt builds up a concentration gradient near the membrane surface as shown in the figure below. The flux of salt across the membrane F_s is equal to the difference between: (1) the rate of salt arrival through concentration by the water flux arriving at the membrane surface; and (2) the rate of salt removal from the membrane surface through diffusion back into the bulk liquid.

The increase in salt concentration at the membrane surface--concentration polarization--has two deleterious effects: (1) an increase in C_b increases in equation 1; hence, the water flux across the membrane for a given applied P is reduced; and (2) an increase in C_b gives a higher concentration difference driving force for passage of salt through the membrane in equation 2; hence, the separation factor between water and salt for the process is reduced.

All these effects increase the capital cost and the power requirements per unit of potable water produced. Concentration polarization cannot be eliminated completely in any reverse osmosis process; its magnitude, however, can be reduced in two ways: (1) the bulk solution can be made turbulent to keep the stagnant boundary layer at the membrane surface as thin as possible; and (2) entrance effects can be utilized by using thin channels in the lamina flow region. Commercially available units operate in the turbulent region.

ENGINEERING PROBLEMS AND DESIGN TASKS

The Burns and Roe report identified several difficult engineering problems in the design of a reliable, low cost reverse osmosis system. Some of the more difficult design tasks are:

a. Supporting a fragile membrane to withstand differential pressures of 250-1,000 psi.

b. Preventing the high-pressure feed and brine streams from contact with the low-pressure product water.

c. Obtaining a sufficiently high packaging density to minimize pressure vessel costs.

d. Minimizing concentration polarization and fouling through design of the feed channels.

e. Avoiding parasitic pressure drops in the feed, brine, and product streams.

f. Minimizing membrane replacement costs.

Attempts to solve these problems while meeting economic and reliability criteria have led to four different module designs:

1. Plate and Frame
2. Large Tubes - Tubular R.O.
3. Spiral Wound Membranes
4. Hollow-Fine Fiber Membranes

Each configuration is currently in use for water recovery from various types of wastewater or solutions.

Cellulose acetate and nylon are used as membrane materials. Reverse osmosis units can be arranged either in parallel to provide adequate hydraulic capacity or in series to effect the degree of demineralization. A scale-free quality feed is required for efficient operation of a reverse osmosis unit and, hence, feedwater pre-treatment is usually necessary--or was until seeded slurry tubular R.O. was demonstrated.

R.O. MEMBRANES

The ideal membrane for desalination by reverse osmosis would consist of a thin, inperfection-free film of polymeric material. The transport properties of the material would be such that water can pass through with little hindrance, while presenting a virtually impermeable barrier to salts.

Most polymers approximate this ideal behavior by exhibiting different flow rates or different permeabilities to water and salts. In order for water and simple salts to be transported across the barrier, they must first dissolve into the polymer material. Once dissolved, passage through the polymeric barrier is controlled by diffusion with different ions having different rates of diffusion. This model of transport is commonly referred to as the solution-diffusion model.

To provide a large flowrate of water, and R.O. membrane must be:

- Extremely thin (typically a few hundred angstroms).
- Extremely strong, which requires special support methods.
- Have as large a surface area as possible.
- Be resistant to scaling.
- Be chemically stable to the solution chemistry.
- Be chemically stable to Cl_2 used as a biocide in feedwater.

Support systems have included woven and unwoven fabric, resin starred fiberglass, porous ceramic and metals, hemp paper, and porous plastic.

Commercial R.O. polymer candidates to date have been made from cellulose diacetate (CA), cellulose triacetate (CTA), blends of diacetate and triacetate, polyamide (PA), a nylon-type material, and more recently, composite membranes of polyamide and polyurea. Cellulose acetate, the standard industry "workhorse" is a high flux, low salt rejection membrane which works satisfactorily for brackish water desalination between pH 5-7. Hydrolysis of cellulose acetate reaches a minimum at pH 5 and increases with temperature.

Numerous membrane research and development companies have developed improved membrane materials. These include Albany International who has developed a new sulfonated polysulfonated membrane which is stable from pH 2-12 up to 90°C' and resists Cl_2 attack.

A. D. LITTLE, INC., R.O. MODULE COMPARISON CHARTS

J. D. Birkett of Arthur D. Little compared 125 membrane modules from twelve manufacturers. He computed the flux per unit volume of module and pressure. Membrane manufacturers usually compare flux on the basis of unit area of membrane, but the user is more interested in flux per unit volume of the equipment. BIRKETT (1983) presented the curves showing "pragmatic flux" = $g\ d^{-1}\ ft^{-3}\ PSI^{-1}$. His comparison bring manufacturer data into a comparable format which would be useful in making a preliminary selection of membranes for testing in a pilot plant program.

BIRKETT (1983) can be reached as follows to request copies of his pragmatic flux comparison charts:

Telex: 921436

R.O. MEMBRANE LIFE EXPECTANCY

LEGER (1983) and others have pointed out that the life of R.O. membranes should range from 2-6 years. Their life, their flux, and salt rejection performance is mainly dependent on two factors:

1. Fouling which results in decreased permeate flux and, depending on the nature and type of fouling, either an increase or decrease in salt rejection according to BELFORT and ALTENA (1983).

2. Chemical and biological degradation of the active membrane surface which is characterized by an increase in permeate flux and a decrease in salt rejection.

About 150 small R.O. systems have been installed on the Witwatersrand and of those, few kept adequate records. However, the longest production life recorded was 7,400 hours which is equivalent to 10.5 months continuous operation--much shorter than they should last. Permeate quality (conductivity) was the criterion used to determine the need for membrane replacement. Bacteria attack cellulose acetate membranes if feedwater is not sterilized and unless the pH is adjusted, CA membranes also hydrolyze.

FilmTec manufactures a wide range of membranes, some of which are advanced and sophisticated. Their FT-30 membrane is non-cellulosic and is of a thin-film composite configuration. It satisfies the main requirement of having high flux and excellent salt rejection but, in addition, it is chemically stable, can operate over a broad pH range, and is partially resistant to chlorine exposure and shows good stability at high feedwater termperatures. The latter characteristics facilitate both acid and caustic cleaning, an important consideration under fouling conditions. The membrane was described by LARSON, et al. (1983) at the Florence conference on desalination. The FilmTec FT-30 spiralwound membrane is made of an 0.2 m polyamide barrier layer over a 50 m microporous polysulfone support supported by a 125 m polyester web. LARSON, et al. (1983) showed that the flux and salt rejection of their FT-30 membrane is pH dependent, with a maximum at pH 8.

Literature on commercially available membranes and membrane fabrication and testing for R.O. is very extensive. The Japanese have made major advances in this area as have a handful of U.S. companies. The following test list suppliers of commercial R.O. membrane modules and also companies known to be involved in R&D of improved membranes.

The Filmtec pressure vessel illustrated here costs about $3,000 and can accommodate three R.O. modules, each costing $2-3,000 each. That is, the Tube capable of yielding 17,600 gpd (67 m^3/d) of permeate would cost about $10,500. A 20' pressure vessel with 6 modules costing $21,000 could produce 30,000 gpd (110 m^3/d), with pump, frame, etc. extra.

FILMTEC ANNOUNCES

3-ELEMENT SEAWATER RO MODULE

For single-pass seawater desalting applications where space is limited, such as shipboard use. Made exclusively for FilmTec Corporation by Advanced Structures.

BAIRINJI, et al. (1983) described the characteristics and operating history of cellulose acetate membranes in which performance and durability were improved by using new additives. The membrane is an asymetric structure reinforced by fabric and is wound in a spiral-type configuration which differs from other spiral-wound elements.

Toray Industries also manufactures composite membranes with 0.2 u protective layers, 300 Å salt barrier layer and porous supporting membranes of polysulphone. The Toray synthetic composite membrane PEC 1000 offers the following advantages:

1) High Salt Rejection
2) High Flux Rate
3) High Temperature and Pressure Durability; however, dechlorination and O_2 removal is necessary.

The Water Research Promotion Council at Chigasaka, Japan, has tested Toray membrane modules.

Reverse Osmosis at a Glance

When fluids of different degrees of concentration are separated by a semi-permeable membrane, the water permeates through the membrane from the dilute solution into the concentrated solution. This is known as *Osmosis.*

The osmotic flow continues until a state of equilibrium is reached. Once equilibrium is attained, the difference in fluid level becomes equal to what is known as *Osmotic Pressure* of the solutions.

Should pressure in excess of osmotic pressure be applied to the concentrated solution, the water in this solution will permeate into the dilute solution. This is called *Reverse Osmosis,* a process involving neither phase transition nor chemical reactions. Reverse osmosis process can thus be applied to any water purification process requiring the separation of fluids into permeate and concentrate forms.

Toray Reverse Osmosis Modules: Description

Reverse osmosis process requires the use of modules, of which there are three types on the market. Toray Modules are the spiral type and, as you can see on the following comparative table, are distinguished by economy, high performance and other features compared to the tubular and hollow fiber types.

Item / Module Type	Toray Spiral	Tubular	Hollow Fiber
Water Recovery Ratio and Efficiency	High	Low	Moderate
Product Flow Rate (Flux) per Module	Moderate	Small	Large
Pre-Treatment and Membrane Cleaning	Simple	Simple	Complicated and Laborious
Quality and Level of Operation Required	Stable and Easy Operation	Stable and Easy Operation	Much Attention Required
Water Cost	Low	High	Low

BINTECH (PTY) LTD. manufactures a highly innovative low-cost plastic supported tubular R.O. cellulose acetate membrane module and system. Each module is capable of producing 1 m^3/d permeate. These modules were installed on the RCC seeded slurry test plant at East Rand Proprietory Mines Ltd. acid mine drainage desalination demo facility in South Africa. Bintech R.O. modules are installed for seawater desalination at Robben Island off Cape Town and for sewage water reclamation at Port Elizabeth, South Africa, as well as in an experimental unit for preparation of boiler feedwater at Vaal Reefs Exploration and Mining Co., Orkney, Transvaal.

Mr. W. Kofod Nielsen
Division Manager,
Membrane Science

This division of Danish Sukerfabriken manufactures plate and frame R.O. membranes and systems primarily to treat cheesewhey.

R.O. SYSTEMS AND COMMERCIAL EXAMPLES

There are many companies that build reverse osmosis systems around commercially available R.O. modules discussed above. These applications vary from hand pumped miniature systems to provide emergency drinking water for lifeboats to 20,000 m^3/d and larger seawater desalination systems such as the one at Malta. The U.S.A. is constructing a mammoth R.O. system at Yuma, Arizona, to reduce the salt content of the Colorado River before it flows into Mexico. The Yuma desalting test program at the Yuma Desalting Test Facility tested eight reverse osmosis units and four ED units accumulating 120,000 hours of operating time between November, 1974, and April, 1977, operating on pretreated brackish water from the Wellton-Mohawk Irrigation and Drainage District. This feedwater has a salinity in excess of 3,500 mg/l. Their test results not reported here are useful.

There are several system configurations that can be considered, depending on the nature of the feed and the quality objectives of the product.

Most conventional systems for desalination of brackish water require a pretreatment plant for disinfection to inhibit bacterial action, pH adjust, removal of iron and manganese by lime treatment, softening, Cl_2 dechlorination, and final pH adjustment to around 5.5, etc. as needed.

The actual R.O. system may be a combination of modules in series and in parallel. The seeded slurry R.O. system arrangement incorporates a special slurry recirculation system.

Advanced system designed for maximum recovery and minimum concentrate volume may combine a pretreatment system, R.O. system (several series systems in parallel) followed by an evaporator for brine concentrate treatment and further recovery of water.

The only two R.O. systems observed in operation to treat mine and mill effluents were:

1) Seed slurry R.O. pilot plant at 5.0 m^3/d at East Rand Proprietory Mines Ltd. on mine drainage (Rand Mines). See the Appendix I trip report.

2) Cass Africa (Pty) Ltd. conventional R.O. System to treat utilities water effluent at the Rustenburg Refinery (Platinum) in South Africa, also described in an Appendix I trip report.

Companies that design and install reverse osmosis water treatment systems include:

TYPICAL R.O. PERFORMANCE

Conventional R.O. performance in seawater desalination is typically 30-35%. Since there is an unlimited supply of feed and a cost-free disposal opportunity, there is little or no incentive to tackle the problems of recovering more than this.

Conventional R.O. processes recover 60-70% from brackish water before the concentrate becomes so concentrated as to present problems. These could be overcome by retreating the concentrate, depending on its gypsum concentration to squeeze additional recovery, perhaps to 80%. In general, R.O. can treat $CaSO_4$-containing water until the $CaSO_4$ concentration in the concentrate reaches 300% of saturation which is the maximum that can be kept in solution by anti-scaling agents. The recovery at which this level in the concentrate is reached is generally as far as one can safely go before the membrane would become fouled.

Seeded slurry R.O. has been demonstrated on a scaling $CaSO_4$-containing minewater to achieve over 95% recovery.

Now, you know why Toray Modules are ideal for reverse osmosis plants

You save on energy.

Compared to other desalting processes, reverse osmosis process gives you savings on energy because the process needs only compression energy and no phase transition. Furthermore, Toray Reverse Osmosis Process provides the highest recovery ratio and requires less energy than other reverse osmosis processes.

You save on space.

Toray Spiral Wound Reverse Osmosis Modules are compact, high-membrane-density modules, thus requiring less space for installation.

Operation is simple.

Toray Process does not require any complicated plant installation. "Start up" or "Shut down" requires only to switch ON/OFF – no special training is required.

Maintenace is easy.

There is little trouble in the operation and the maintenance is very simple and easy with periodical module exchange; you do not need specially skilled operators.

You can get the modules promptly.

Toray Modules are promptly supplied at short notice. We can supply you with a complete reverse osmosis plant in no time at all.

Brackish Water Desalination and Wastewater Treatment

This technique, which also utilizes Toray Spiral Wound Module, offers such standout features as high recovery operation due to uniform flow and less polarization. The module itself is tough, assuring low maintenance cost.
The large membrane surface area is complemented by large permeate flow. The product water itself is characterized by a high level of purity, allowing its use in potable water or industrial water.

P-Type Modules

Designed for special applications, this type of module produces ultra-pure and germ-free water for use in the electronics and medical industries. It is available in 4-inch and 8-inch configurations. Reverse osmosis performance is equivalent to that of standard types.

Basic Configuration

Exterior View of Module and Direction of Flows

Materials of Module

Direction of Flows

Module Pack Assembly in a Pressure Vessel

Main Advantages of Toray Spiral Wound Modules

1. The high water speed of the brine on the membrane's surface minimizes possible polarization trouble.
2. Reverse osmosis performance does not deteriorate, even when the recovery ratio is increased or the brine flow rate is reduced.
3. There is no dead space trouble as the position of the brine seal is different from that of other spiral wound modules.
4. There is no telescope deformation trouble.

Major Applications

1. Desalination of seawater provides potable water in isolated islands or coastal areas.
2. Desalination of brackish water provides potable water or industrial water.
3. Wastewater reclamation provides industrial water.
4. Production of ultrapure water for electronics industry or germ free water for medical and pharmaceutical industries.
5. Recovery of valuable and useful substances from wastewater in food and painting industries.
6. Various solutions containing saccarides, proteins and enzymes can be concentrated.

Toray Reverse Osmosis Process in Action

Seawater Desalination

Toray's two-stage seawater desalination technique is distinguished by superbly constant and stable performance to produce high quality sweet water. Thanks to its unique module structure, Toray Modules assure a high recovery ratio, minimized polarization effect and no telescopic deformation whatsoever. The overall performance is the world's most outstanding and requires the use of very little energy, further enhancing the system's economy.

CAPE CORAL, FLORIDA
REVERSE OSMOSIS PLANT

Operating Performance Summary Permeators

May, 1983

by

DOW CHEMICAL COMPANY

I. INTRODUCTION

Since start-up of the 3 MGD DOWEX RO-20K reverse osmosis system at Cape Coral, Florida, in March 1977, the performance of this water treatment plant has far exceeded original expectations. During this time, the DOWEX reverse osmosis system has operated virtually flawlessly with a minimum of pretreatment and without cleaning for the first six years of operation. (Two skids of 0.5 MGD each were cleaned by Basic Technologies in March 1983.) In addition, none of the original 132 permeators supplied by The Dow Chemical Company has had to be replaced.

In June of 1980, Cape Coral expanded their RO capacity from 3 MGD to 5 MGD. Another hollow fiber membrane consisting of polyamide was chosen for the expansion rather than DOWEX RO-20K which is based on cellulose triacetate. (Note that 1980, the year of the expansion, was one year before Dow commercialized DOWEX Low Pressure permeators which would have allowed a 40% savings in energy costs.)

The City of Cape Coral has received a number of awards from various organizations relating to both the operation of the facility itself as well as the efforts of the city to effectively manage their water resources.

II. SYSTEM DESIGN

Figure 1 is a simplified flow diagram of the RO system. The original 3 MGD system consisted of six wells supplying approximately 1300 ppm TDS feedwater to the water treatment plant and has since been expanded to more than 10 wells. The pretreatment of the combined well water consists of acidification with sulfuric acid to avoid calcium carbonate precipitation, addition of sodium hexametaphosphate for sulfate salt scale control, and filtration through 5 micron cartridge filters. The water pressure is increased at each of six skids and sent to the RO modules. Each skid consists of 22 DOWEX RO 20-K permeators in a 16x6 array equipped with a Goulds vertical turbine pump, model 10ALC, and 250 horsepower motor. The product water from each stage of the RO system is combined, blended with raw water and sent to a forced draft degasifier to remove H_2S and CO_2. The pH is adjusted with caustic, then the water is chlorinated and sent to the ground storage tanks for subsequent distribution. Auxiliary features include an automatic flush system when the modules are shut down and a cleaning system.

III. OPERATING COSTS AND SYSTEM PERFORMANCE

The operating costs for the reverse osmosis system at Cape Coral have been summarized in Table 1. Note that most of the increase in operating cost over time was due to the increased cost of electricity.

Comparative operating data for the DOWEX RO-20K permeators versus the other hollow fiber permeators have been documented in Table 2. Note that six-year old DOWEX RO-20K permeators compare quite favorable with the three-year old other hollow fiber permeators in terms of salt rejection (83% versus 84%) and have significantly higher productivity (458M gpd versus 405M gpd) at a lower feed pressure (320 psi versus 390 psi).

As part of a continuing program between Dow and the City of Cape Coral to help maximize operating efficiency of the entire RO plant and therefore reduce operating costs, two studies have been undertaken. First, starting in December 1982, one skid has been operated at 75% recovery on a continuous basis instead of the design recovery of 65%. Increased recovery appeared technically feasible because the original system design was dictated by a projected degradation in feedwater quality which has not materialized. After three months of operation at higher recovery with no loss in performance, recovery is now being increased on additional skids.

Secondly, in April 1983, Basic Technologies, Inc., cleaned two of the Dow skids including the skid which had operated at 75% recovery and the skid which had been used as the control and had operated at 65% recovery. After cleaning and treatment, salt rejection of the two skids were 89.5% and 90.0% respectively, which is very close to the performance of these skids after only three years of operation. The remaining skids can now be cleaned by the city at their convenience.

The performance data from the City of Cape Coral clearly show that RO is a cost effective means for treating brackish water and can indeed provide a reliable source of quality product water. In addition, the history of Cape Coral also shows that with proper operator attention to detail, the life expectancy for a RO system can not only be met but can be exceeded.

TABLE 1

REVERSE OSMOSIS SYSTEM[1] OPERATING COST SUMMARY FOR

CITY OF CAPE CORAL, 1977-1982

	Cents/1,000 Gallons				
	1977-78	1978-79	1979-80	1980-81	1981-82
H_2SO_4	3.0	3.4	4.0	5.5	6.0
Caustic	1.1	1.7	2.1	2.0	1.0
Sodium Hexametaphosphate	1.2	0.9	1.8	1.0	3.0
Chlorine	1.5	0.4	0.4	0.3	0.3
Electrical	26.3	34.5	42.0	47.0	56.0
Labor	11.2	10.4	9.6	10.5	13.0
Total	44.3	51.3	59.9	66.3	79.3

[1]Reverse Osmosis system capacity was 3 MGD from 1977-1980 and 5 MGD from 1980 to the present. Capacity utilization averaged about 55% over this time period.

FIGURE 1 Process flow diagram of the Cape Coral reverse osmosis plant.

CITY OF VENICE, FLORIDA
R.O. PLANT-OPERATING PERFORMANCE SUMMARY

Using Dowex Low Pressure Permeators

May, 1983

by

DOW CHEMICAL COMPANY

I. INTRODUCTION

The City of Venice, Florida, started up their first reverse osmosis water treatment plant using a standard pressure polyamide hollow fiber type permeator in 1975. In 1981 when their need for potable water increased, DOWEX Low Pressure permeators were chosen for the 1 MGD expansion primarily because of the low pressure advantage and resultant 40% energy savings. This expansion started up in September 1982 and was installed on schedule by Basic Technologies, Inc., of Riviera Beach, Florida.

II. SYSTEM DESIGN

The Venice system utilizes two water treatment technologies, lime softening and reverse osmosis. Traditionally, the lime softening process has consisted of the addition of alum, lime, and caustic for the precipitation of carbonate and non-carbonate hardness. Pretreatment for the RO plant consists of sulfuric acid addition to prevent carbonate scale, sodium hexametaphosphate for sulfate scale control (Ca, Mg, Ba, and Sr) and 5μ cartridge filtration. Product water from the two plants is combined, degasified, and clorinated prior to storage.

The Dowex Low Pressure RO system consists of 52 permeators in a 1 stage array operating at 55% recovery.

III. OPERATING COSTS AND SYSTEM PERFORMANCE

The combined operating costs for the reverse osmosis plant have been outlined for you in Table 1 for three representative months of operation. The data from August 1982 (before start-up of the low pressure system) is included as a reference point for before and after comparisons. Difference between electrical cost in October and January are due to variation in use of the old high pressure system. This variation reflects the fact that the DOWEX Low Pressure system is used 100% of the time while the high pressure system is used for peak demand periods only.

System performance has been documented in Table 2 for the DOWEX Low Pressure skid only. As you can see, 97% salt rejection is being achieved at only about 230 psi operating pressure after eight months of operation.

The energy savings from low pressure operation have been estimated by the engineering firm, Post, Buckley, Schuh, and Jernigan, at about $80M/yr. In addition, permeate quality from the DOWEX Low Pressure system is so

much better than the old standard pressure system (85 ppm versus 250 ppm) that the city has been able to reduce the amount of caustic used in the lime softening plant for removal of non-carbonate hardness, and still meet their blended water quality standards. The city has estimated the savings in lower caustic usage at about $100M/yr. Therefore, the total savings in operating costs to the City of Venice by installing the 1 MGD DOWEX Low Pressue RO system is estimated at a very significant $180M/yr.

TABLE 1

REVERSE OSMOSIS SYSTEM[1] OPERATING COST FOR

CITY OF VENICE, FLORIDA

Item	Cost (Cents)/Thousand Daily Gallons		
	Aug 82	Oct 82	Jan 83

TORAY PEC-1000 COMPOSITE MEMBRANE MODULE

for desalination and seperation process

800m³/day (212,000GPD), Single-Stage Seawater R.O. Desalination Plant at Chigasaki (Water Reuse Promotion Center), Japan.

In July 1981, 800m³/day (212,000GPD) single-stage seawater desalination plant using PEC-1000 membrane elements (SP-120) started operation at Chigasaki Plants of W.R.P.C.

The unit has operated in excess of 1200 hours (since July 1981), and the performance maintained without any significant decline in salt rejection and water flux. Permeate purity is constantly kept less than 130ppm TDS and water flux maintained constantly at 800m³/day (212,000GPD), 53~55kg/m², 20~29℃, 40% recovery and 3.5% seawater concentration. The system operates with 29 Today modules containing 174elements of SP-120.

Flow diagram of 800m³/day (212,000GPD) single-stage seawater R.O. desalination plant at W.R.P.C. - Using Toray PEC-1000 Membrane Module (SP-120)

Toray PEC-1000 Composite Membrane

Toray's new composite membrane, designated PEC-1000, has been developed from many years of reserch, development, testing and represents the latest in membrane technology.

PEC-1000 has been specially designed for complete single-stage seawater desalination and takes into consideration both membrane performance and mechanical structure.

Complete single-stage seawater desalination permits low TDS permeate from high temperature - high salinity seawater feed and at high recovery rate of feedwater.

To meet the challenge of dependability and durability in basic seawater membrane performance, Toray has built into its design, the highest salt rejection,permeate flow rate, and durability for high temperature and high pressure operation. This combined quality can not be found in other conventional single-stage, partial single-stage or double-stage membranes.

The PEC-1000 membrane is made of a composite type structure consisting of, (1) a thin 300 Å salt barrier layer(being thicker than the other composite membranes), (2) a porous supporting membrane made of polysulfone and, (3) the composite structure being reinforced by a polymeric material and fabric.

Main Advantages of Toray PEC-1000 Composite Membrane Modules

Toray PEC-1000 Composite Membrance Module was developed especially for uses in **single stage seawater desalination** and in **recovery of valuable organic materials.** It has the following outstanding features:

1. High salt rejection, reaching average **99.7%** in seawater desalination.
2. High organic materials rejection, reaching more than **92%** in ethanol recovery.
3. Wide range of operating temperatures, with a maximum operating temperature of **40°C (104°F)**.
4. Wide range of operating pressures, with a maximum operating pressures of **70kg/cm² (1000 psi)**.
5. Wide pH range of **pH 1 through 12**.

Major Applications

Toray PEC-1000 Composite Membrane Module was designed to be used in the following major applications:

1. **Complete single stage seawater desalination** to produce fresh water for drinking, industrial and agricultural use.
2. Concentration and recovery of valuable organic materials from dilute aqueous solution.

ALBANY INTERNATIONAL

Information Memo

December 6, 1982

Company Launches New Business Based On Membrane Technology

After nearly ten years in development, Albany International's reverse osmosis/membrane separation technology is starting to come to fruition. We recently licensed a portion of this technology to Millipore Corporation, the world leader in separations technology based in Bedford, Massachusetts, and shortly thereafter established our Membrane Development Venture in Norwood to further develop and commercialize these purification processes.

On November 2, Albany International announced its agreement with Millipore to grant that company an exclusive, worldwide license to use our patents and know-how for certain applications in liquid purification. In turn, we have received an initial payment of $2 million and will receive royalties of five percent on all product sales through 1998. Under the terms of the agreement, we retain the right to exploit this technology in other liquid applications and in gas separations.

A week later, the company announced the formation of the Membrane Development Venture to continue to explore applications for the technology and to pursue avenues to its commercialization. Heading up the new business is Mike Coplan, formerly Senior Corporate Scientist, who will serve as General Manager. Mike has been instrumental in this research effort since its inception. Reporting to Mike will be three Assistant Managers, Ben Bikson, Doug Burchesky and Fred Bilewski, with responsibility for Laboratory, Production, and Administration and Engineering, respectively. Ben, Doug and Fred were previously Senior Research Associates.

The venture's specific objectives are to attempt to generate membrane separation packages for license, sale, joint venture or internal development; to perform collaborative research with potential partners or principal users; to seek and exploit opportunities for joint development of advanced methods and products in the membrane separations technology area; and to advance Albany International's technological expertise in the entire area.

Albany International Research Company has been actively exploring new materials and processes in reverse osmosis for a number of years now. The basic technology employs bundles of tiny hollow fibers coated with a semipermeable membrane which, under pressure, allows certain solutes to pass through while rejecting other dissolved materials.

(continued)

These hollow fibers, magnified about 75 times, form the basis of Albany International's reverse osmosis/membrane separation technology for liquid purification and gas separation. Our unique method of preparing the porous fiber substrate enables us to use very thin membrane coatings which enhance the separation process.

*Reprinted from Albany International's management newsletter.

Information Memo

Company Launches New Business from page 1

Much of our work in this area has evolved from the Research Company's hollow fiber technology development, which dates back to 1964-65. In more recent years, efforts have been concentrated on developing a superior membrane that would be durable in chlorine, operable over wide pH ranges and at high temperatures.

Membrane separation processes can be used to separate water from other liquids, remove substances such as salt and metals from liquids, concentrate substances such as dissolved sugar, and separate gases.

Albany International will be seeking opportunities to exploit this technology in several liquid applications, such as desalination of seawater, treatment of process and waste streams generated in the fields of mining and mineral extraction, and petroleum and synfuel production and refining.

In addition, the corporation will explore applications in gas separations, with emphasis on several energy-related areas. These include production of oxygen-enriched air for increased efficiency of fossil fuel combustion in smelting and other industries, the use of carbon dioxide for rejuvenation of dormant oil wells, and removal of sour gas components from natural gas.

Reverse osmosis/membrane separation technology is still relatively new — the first reverse osmosis membranes were developed only about 20 years ago and the process has been commercially viable only since about 1969 — but the opportunities for growth in this area are great. We believe our superior, proprietary technology gives us a good edge over the competition.

A reverse osmosis module for water purification is tested at our Norwood laboratory. Liquid to be purified is pumped into the module, consisting of a bundle of hollow fibers inside a fiberglass reinforced plastic pressure shell, at pressures up to 1000 psi. The pure water, or permeate, and the concentrate emerge in two separate streams from the lower end of the module.

ALBANY INTERNATIONAL RO MEMBRANE FEATURES

COMPOSITE MEMBRANE MAKES POSSIBLE CHEMICAL TAILORING FOR SPECIFIC USES.

HOLLOW FIBER CAPABLE OF OPERATING OVER RANGE FROM HOUSEHOLD PRESSURE TO 1000 PSI OR MORE.

SYSTEM DURABLE TO STERILIZATION BY 100 PPM CL_2, AND LONG-TERM EXPOSURE TO 5 PPM CL_2, pH 5-8.

CHEMICAL RESISTANCE PERMITS OPERATING AGAINST FEEDS HAVING pH LEVELS AS LOW AS 1 AND AS HIGH AS 12+.

TEMPERATURE STABILITY UP TO 80°C.

SEAWATER DURABILITY TESTED TO 25,000 HOURS (AS OF 1/1/83).

UNIQUE MODULE DESIGN AND FLUID DYNAMIC FEATURES REDUCE FOULING SUSCEPTIBILITY.

Attention : Hans von Michaelis

Dear Sir

TUBULAR REVERSE OSMOSIS/WATER TREATMENT

I am responding to your letter 16 November 1984 to Mr D.B. (Skottie) Smit. Your comments about the mining industry although brief and to the point confirm my feelings on the mining industry insofar as desalination is concerned. However I am hoping that the next five years will be the transition period from traditional water treatment methods to the inclusion of large scale desalination at the mines.

Our most recent successes have been outside of the mining industry. During 1984 we ran a pilot plant at the Grootvlei power station with very good results on cooling tower recycle waters. This in turn led to the award of a 6,5mℓ/d Effluent Concentrator Plant contract at Lethabo (Escom).

The main contractor in the venture is Foster Wheeler Energy Ltd with Bakke being the sub-contractor insofar as technology is concerned. During 1984 we also installed and commissioned two plants operating on brakish waters in remote areas. The one plant has to contend with in excess of 5 000 TDS and has a permeate capacity of 360 m^3/day. The other plant is operating on a water with a very high iron content in the arid north-west Cape region. At Port Elizabeth Municipality the City Engineers Dept. have run one of our pilot plants for sixteen months, at time of writing, on secondary sewage effluent from activated sludge plant filtration, with a view to producing potable water for the future. Comprehensive analysis indicates a water quality from this plant well within SABS potable standards - in fact better than anything we are drinking at the moment. The Anglo American Research Laboratories intend to run a similar pilot study during 1985 - possibly on a mix of secondary sewage effluents and other waters.

The Water Research Commission has taken a keen interest at what is happening at P.E., and might soon be involved in part sponsoring a commercial project to produce process water for industry in P.E.

Enclosed is a brochure recently printed plus two photographs of our third generation pilot plant. The fourth generation pilot plants are fairly similar, however for some reason I do not have any photographs available. We have since improved our coupling and module array design.

Directors/Direkteure: J. A. LOUW, D. B. SMIT, A. R. D. KOCH, P. A. HATTINGH.

As far as Seeded Slurry Reverse Osmosis is concerned things are going well. I suggest you contact Herb Rothschild in Seattle at RCC to get the status of present projects.

Your asked for information on prices - what I can tell you is that our operating costs including the capital component vary between 50 cents (SA) and one Rand (SA) for medium to large applications. Both operating and capital costs are highly variable depending on feed waters, design parameters, size, recovery required, rejection required etc. At a later stage I will draw up some standard comparisons for categorised applications.

Thank you for your interest.

Yours Sincerely

PETER SWART
COMMERCIAL MANAGER : MEMBRATEK

P.S. Skottie and Johan send their regards.

PRETREATMENT

The purpose of pretreating feedwater to cellulose acetate R.O. modules is to obtain optimum plant performance and membrane life:

1) Removal of colloidal substances that may foul the membranes and reduce plant output.

2) To remove, modify, or inhibit sparingly soluble substances that may precipitate and foul the membrane surface, bearing in mind that ions in the concentrate are concentrated in proportion to the degree of recovery of permeate achieved, e.g., if recovery is 80%, then the salt concentration in the concentrate (20%) will be increased by about 500%, assuming salt rejection is 100%).

3) To remove or modify chemical such as chlorine and other oxidants which may chemically destroy some membrane types.

4) To prevent bacterial growth and consequent membrane fouling or degradation.

Typical pretreatment measures required:

1. Chlorination to destroy bacteria and algae growth.

2. Lime treatment and settling to remove manganese and iron.

3. pH adjustment to the pH 5-6 range. Higher pH than pH 7 results in degradation of CA membranes. Rand Water Board water, for example, is typically in excess of pH 8. Calcium carbonate and magnesium scale is also controlled by keeping the pH below 6.7. pH adjustment to prevent hydrolysis of the membrane is not required for polyamide or polysulfonate membranes.

4. Removal of residual chlorine by sodium bisulfite addition or activated carbon column.

WATER SOFTENING

Water softening reduces the calcium and magnesium concentration in feedwater and minimizes the risk of scaling.

SCALE INHIBITORS

Sodium hexametaphosphate is used as a scale inhibitor. Inhibitors are required when conventional plants operate at high recoveries to prevent calcium carbonate and calcium sulfate from precipitating on the membrane surface. However, most R.O. units are operated at low recoveries. Only when the purpose would be recover dischargable water from industrial or minewater, for example, would the goal to be optimize recovery and reduce the volume of concentrate to a minimum.

DECHLORINATION

Polyamide and some composite membranes require dechlorination of feedwater (e.g., reduction by sodium metabisulfite addition or by activated carbon) to prevent oxidation of the membrane.

MEMBRANE CLEANING

Membranes at one South African plant were replaced seven times in seventeen months following startup. When a weekly membrane cleaning schedule, using EDTA and citric acid, was started, the eighth membrane set lasted 14 calendar months (7,600 hours of operation).

Some membrane manufacturers recommend that R.O. membranes should be cleaned when the flux has decreased by 10%, or the salt passage has increased by 25%.

PLANT OVERDESIGN

Often plants may be overdesigned in the mistaken belief that this will compensate for flux decline due to fouling.

When fouling occurs, permeate quality also generally deteriorates as flux drops. This is because the salt rejection by the membrane is related to permeate flux (JOHNSON, et al, 1966), and foulant deposits on the membrane surface cause increased concentration polarization which in turn results in an increase in solute passage (SHEPPARD and THOMAS, 1971).

Chemical degradation of membranes continues whether the plant is in operation or not. This process is a function of time, not permeate production. When the plant is off-line, membranes tend to deteriorate more quickly due to microbiological growth, particularly when they are not preserved (e.g., by formaldehyde).

Foulant deposits become more difficult to remove with time. Over capacity means that plants initially do not require regular cleaning since production requirements are met despite fouling. However, when cleaning is implemented, it will probably not be as effective in restoring productivity due to the "aging" of foulant deposits.

LEGER (1983) points out that the installation of suitable storage tanks, instrumentation, and controls to allow semi-continuous unattended operation would result in a cost savings due to fewer membrane replacements and would probably provide better quality water at a lower cost.

Membranes should always be flushed before shutdown to avoid precipitation of salts concentrated at the membrane surface.

MEMBRANE FOULING

LEGER (1983) analyzed foulant deposits on membrane modules from several desalination units treating Johannesburg tapwater. At some plants, the main foulant turned out to be calcium carbonate, probably because the pH of the feed had not been adjusted. At other plants, the fouling contained high levels of aluminum and silica which indicated that fouling may have been caused by clay colloids or particulates, by precipitation of aluminum hydroxide, aluminum silicate, and colloidal silica, or combinations thereof.

Iron and zinc were significant components of deposits on other membranes, and LEGER (1983) concluded that the source of these ions must have been galvanized iron pipes used for water reticulation. Iron fouling may be removed by cleaning with chelates such as EDTA or citric acid. If operated at a slightly acid pH, say pH 5, ions such as zinc, copper, lead, cadmium, and nickel will be kept in solution.

At some of the plants tested, organic fouling was identified, the nature of which was still under investigation when he presented his paper.

The conclusion drawn from LEGER (1983) is that if such significant problems were encountered in treating tapwater by R.O., then imagine the potential problems to be catered for in treating mine drainage or mill effluents. In this respect, the seeded slurry R.O. system proposed by Resources Conservation Company is that much more attractive.

SEEDED SLURRY REVERSE OSMOSIS

Recycling of slurries to present nucleation points in the treatment of scaling solutions is not a new concept. Seeding is used in filtration of nearly saturated or supersaturated

solutions, it is used in clarifiers and settlers, e.g., the HDS process, and in cross-flow microfiltration as well as untrafiltration membrane processes. It has also been used to precipitate $CaCO_3$ from recycled in situ uranium leach solutions and in seeded slurry evaporation processes.

Seeded slurry reverse osmosis using tubular R.O. modules was first demonstrated by Resources Conservation Company as described by: HERRIGAL (1984), RCC (1981), KIRCHNER and O'NEIL (1980?), and GOODLOE (1984), all inserted below. See also the trip report on ERPM in Appendix I.

One of the conclusions of this investigation is that seeded slurry reverse Osmosis is the most useful and practical application of membrane processes for the treatment of acid mine drainage and metallurgical process recycle solutions.

Although tubular R.O. modules yield only, say 1 m^3/d permeate compared with 80 m^3/d from holofine-fiber modules of comparable size, seeded slurry R.O. avoids the need for feedwater pretreatment and makes it possible to achieve much higher water recoveries while leaving a much smaller volume of more easily disposed of concentrate. Overall capital costs are likely to be comparable. Overall operating costs are likely to be lower using seeded slurry R.O., and the operation of seeded slurry R.O. systems for the treatment of mine-mill effluents will be very much simpler and easier to operate, i.e., more compatible with the mine-mill environment than the more sophisticated, high-capacity R.O. modules requiring extensive multi-step water treatment steps.

SPIRAL WOUND/HOLOFINE RO MODULES

SEEDED SLURRY RO (TUBULAR MODULES)

Conventional R.O. requires multi-step pretreatment to achieve 80% recovery without fouling the membranes. Seeded slurry R.O. requires no pretreatment to achieve 95%-plus recovery with correspondingly smaller concentrate disposal needs.

REVERSE OSMOSIS COST DATA

There is a relatively wide range in R.O. costs, depending on the scale of operation and how it is to be applied. For example, treatment of tapwater to yield a low TDS permeate for use after ion exchange demineralizing where low R.O. recoveries and cost-free concentrate disposal of cencentrate is possible would be at the low end of the range. These variations are very well illustrated by SCHUTTE (1983) whose chapter entitled "Economic Considerations" was inserted at the end of Chapter 13 to show a comparison of various desalination processes. Desalination of seawater, which has a high TDS level (3.5-4.0%) but where recoveries can be low, and concentrate disposal is cost-free (back to the ocean), usually costs between $4.00-$11.00 per 1,000 U.S. gallons ($1.00-2.80/m^3), depending on the scale of operation and pretreatment required. (Note that desalination of seawater with high natural organic polymer loads along the South West Africa/Namibian coast proved not to b feasible.)

Desalination of brackish water by R.O. for recovery of potable water, excluding concentrate, based on case studies by the Dow Chemical Co. inserted above for a 2 mGD operation, ranged between $0.44-$0.86 per 1,000 g at City of Venice, Florida. Interestingly, the lower cost was for the more recent year (1983).

Bintech (Pty) Ltd. has demonstrated operating costs between R0.50-R1.00/m^3 ($1.90-$3.80/1,000 U.S. g), including capital amortization, for various small-scale operations.

U.S. AID (1980) published a cost estimate for various desalination processes at various plant sizes indicating costs for R.O. desalination of brackish waters at around $1.90/1,000 g ($0.50/m^3).

GLUECKSTERN (1982) compared costs of R.O. and evaporation processes for seawater and brackish waters in Israel and summarized his 1978-1980 data in the graph shown overleaf. His almost two decades of experience in this field make him a valuable reference source:

DR. PINHAS GLUECKSTERN
Mekorot Water Company Ltd.
Post Office Box 20128
Tel Aviv, Israel

It is important to note that where desalination of minewater or mill effluents is the objective of the desalination plant, i.e., to remove salts from effluents, then the disposal of the concentrate is an important consideration and represents an additional cost factor which must be taken into account when comparing alternative system options.

Operating Cost of Eilat Desalting Plants

(1978-1980)

WARNING

1 Caution should be exercised when using these cost data

2 These costs are computed for basic desalination facilities in the USA. These costs include no st[illegible]e capacity and allow for o[illegible] fun[illegible] [illegible] (water develop-ment and brine disposal. If storage capacity is added and/or more complex feedwater or brine facilities are required, o[illegible] all pr[illegible] can significantly increase. This is especially true with brackish water facilities. Construction in locations outside the USA can also add to t[illegible] overall [illegible] A. tual costs of up to 300% (or more) of those shown on this figure (especially at lower capacities) would not be unusual for projects in many deve[illegible]ping a[illegible]

FIGURE 11.2 Generalized unit production cost estimates for desalination processes. (USAID 1980)

FLUID END COMPONENTS

CYLINDER BODY. High strength ductile iron.
CYLINDERS. Tapered fit steel shells with smooth, hard K-Ramic® lining to resist wear and corrosion.
SUCTION AND DISCHARGE. Three large tapped suction ports, two on sides and one front. Two discharge ports are tapped and flanged.
PISTON PACKING MATERIAL. Molded composition Buna-N V-rings.
PISTON ASSEMBLY. V-ring packing is supported by a fabric reinforced phenolic follower. 416ss stud, 303ss pressure ring, 303ss retainer. Entire assembly is attached to piston rod with 304ss cap screw.
SPRING LOADED FLAT VALVES. Positive, fast acting 301ss valves, 302ss valve springs and hardened 420F seats. Seats tapered into body casting for easy removal.
VALVE AND CYLINDER CAPS. Feature recessed neoprene O-rings held in place by heavy bolted clamps. Ductile iron caps have no threads to corrode or hinder easy access to valves and pistons.

POWER END COMPONENTS

GEAR CASE. Made from durable cast iron. Serves as oil reservoir for constant, splash type lubrication of all working parts. Lid removes for easy inspection without draining oil.
PINION AND GEAR. Induction hardened alloy steel. Helical cut and shaved for smooth, quiet and efficient operation.
PINION SHAFT. Gear integral with shaft is made from alloy steel for strength and resistance to fatigue.
BEARINGS. Crankshaft and pinion shaft have tapered roller bearings for minimum friction and power loss.
CONNECTING LINKS. Cast iron with replaceable bronze wrist pin bearings.
CRANKSHAFT JOURNAL BEARINGS. Steel backed babbit inserts.
CROSSHEADS AND PISTON RODS. Crossheads are made from ductile iron. Bronze bushings serve as crosshead pin bearings. Stainless steel piston rods are ground and polished to a smooth finish. Rods are pinned and threaded in perfect alignment with crosshead and cylinder.

Myers high pressure industrial pumps

D65-16CVD/65 GPM/1600 PSI

Designed for high capacity/high pressure applications, the Myers D65-16CVD has established a proven record of reliable service. A triplex, single-acting, reciprocating pump, it has been built to withstand the strain of rugged industrial use. In addition to normal industrial installations, the D65 fulfills the requirements of modern high pressure fire fighting equipment and is recommended for fire pump service.

The pump features a single helical gear reduction drive which provides smooth, quiet and efficient operation. The slow crankshaft speed minimizes parts wear and extends pump life. A splash type oil bath system assures continuous lubrication of all internal parts. The crankshaft may be rotated in either direction for ease of installation.

The high strength ductile iron fluid end permits continuous operation at 65 GPM and 1600 PSI with maximum performance and dependability. All valve and piston assemblies are easily serviced through front and top cylinder body openings. Servicing of both the power and fluid ends can be accomplished without removal of the pump or disturbing the system piping. The heavy duty construction and durability of the D65 will give years of trouble free operation.

SPECIFICATIONS

Rated Capacity	65 GPM @ 376 SPM
Pinion Shaft Speed at Rated Capacity	1487 RPM
Gear Reduction Ratio	3.95:1
Rated Pressure	1600 PSI
Temperature Rating	120°F.*
Cylinder Bore	2.125"
Piston Stroke	3.750"
Suction Size	3" NPT
Discharge Size	1¼" NPT
Pinion Shaft	1⅝" Dia.
Keyway	⅜" x 3/16" Straight
Approximate Weight	525 Lbs.

*If liquid temperatures are to exceed 120°F., consult factory

Myers high pressure industrial pumps

D35-12AVD-2H/35 GPM/1200 PSI

The Myers D35-12AVD-2H is a triplex, single-acting, positive displacement pump for high pressure service. It is designed primarily for pumping water, detergent solutions and similar liquids in an unlimited variety of industrial applications. The heavy duty construction and reliable performance allow this pump to be installed in areas where durability is a must.

The power end utilizes internal single helical gear reduction drive for smooth, quiet and efficient operation. Constant lubrication is assured with a splash type oil bath system. Either direction rotation of the crankshaft permits easier installation. The high strength ductile iron fluid end affords a range of continuous operating pressures up to 1200 PSI. The pump features V-ring packed pistons which permits not only handling of higher temperatures, but offers extended packing life as well.

Slow speed operation of the pump provides minimum wear of parts and extends service life considerably. Maintenance is made easier with fluid and power end components being readily accessible. Excellent performance and serviceability are two outstanding features of all Myers reciprocating pumps.

SPECIFICATIONS

Rated Capacity	35 GPM @ 317 SPM
Rated Pressure	1200 PSI

POMPES GUINARD

TPMDX

pompes guinard patent

the integrated turbo pump unit
for sea water reverse osmosis desalination

MAIN FEATURES :

— Working pressure : up to 70 bars (1020 PSI)
— Flow rate : between 15 m³/h (65 USGPM) and 350 m³/h (1500 USGPM)
— Running speed : 5000 to 10 000 RPM
— Power : up to 600 KW (800 HP)
— Energy recovery : up to 40 PCT

611

INTRODUCTION

POMPES GUINARD is the only pump manufacturer proposing a turbo-pump specifically adapted to the desalination by reverse osmosis : the TPMDX.

This integrated turbo-pump unit, composed of a pump and a turbine back to back, mounted on the same shaft and in the same casing, separated by a hydrostatic bearing is specially designed to meet the requirements of the Reverse Osmosis Desalination.

This is why the TPMDX is the product which offers the most advantages for this application.

This particular design, patented in most countries, insures the best compromise between investment cost and running cost.

MATERIALS

All casing parts	316 L
Hydraulics	316 L with surface treatment
Wear rings	21 % Cr 8 % Ni + Mo + Cu
Shaft Labyrinth	21 % Cr 8 % Ni + Mo + Cu
Hydrostatic bearing	316 L with stellite grade 6
Hydrostatic bearing sleeve	316 L with stellite grade 12

RELIABILITY : ADVANTAGES

— Compactness — Hydrostatic bearing	— Critical speed at 120 PCT of running speed — Very low vibration level (< 4 μ)
— No mechanical seal	— Low maintenance cost
— Actual hydraulics of turbine	— Very high efficiencies — Low back pressure at turbine outlet
— Low liquid speed	— No risk of cavitation — No risk of erosion-corrosion

TOULON DEMONSTRATION BENCH

In order to prove the high qualities of this exclusive energy recovery turbo-pump unit, POMPES GUINARD has constructed a demonstration-test stand in TOULON (FRANCE), in cooperation with "Commissariat à l'Energie Atomique".

This stand consists in :

— A complete TPMDX unit size VI designed for a standard R/O plant of 2.5 million GPD fresh water (5 lines each of 1 500 GPM sea water).
— A pre-treatment system identical to the one standard of the industrial sea water desalination plants.

Characteristics :

Sea water : PH : 6 - 39 000 ppm - Temperature : 30-35° C
Process : R/0 1 000 PSI - Conversion rate : 25 %
TPMDX : Pumped capacity : 1 500 USGPM (340 m³/H)
Turbined capacity : 1 120 USGPM (255 m³/H)
Break horse power : 676 HP (504 Kw)
Energy consumption : 1,8 HP/USGPM (5,9 Kwh/m³) fresh water

For further informations and visit of the TOULON bench, please contact our ANNECY PLANT.

THE SEEDED REVERSE OSMOSIS PROCESS FIELD TESTING

H. R. Herrigel
Vice President - Research
Resources Conservatio Co.
3103 N.E. Northup Way
Bellevue, Washington 98004

The success over the past decade (1970-1980) of the reverse osmosis process for water desalination is impressive. The rapid growth in capacity of R.O. installations since 1973 is seen in Figure 1 [taken from Katz (1)], amounting to about 20 percent of total capacity for all processes by mid-1980. A consideration of the number of installations reveals that by mid-1980, R.O. accounted for about one-half of the total number of installations of all processes.

As would be expected, such success has not been achieved without effort. The earlier literature contains numerous reports of problems, but nowadays, the requirements for a successful application are fairly well established, at least for the typical desalination application. Applications of R.O. to wastewater recovery appear to have more problems. Requirements based on osmotic characteristics of the membranes used and on the colligative properties of the solutions handled have been codified and are subject to rational analysis, prediction and design. Requirements based on chemical and mechanical characteristics of the membrane and the configuration in which it is used, have been established semi-empirically on the basis of tests and experience.

Figure 1. Capacity (Millon Gallons per Day) of Water Desalting Installations over 25,000 GPD

Among others, the standards adopted to prevent plugging, fouling, and scale precipitation fall in this category.

To avoid plugging and fouling by particulate matter, rather stringent requirements are placed on the presence of these materials in the R.O. feed, e.g., a silting density index less than 5.0 for spiral (or 3.0 for hollow fine fiber), or a turbidity less than 0.2 NTU. Standards have tended toward greater stringency in recent years. To achieve such cleanliness, a filtration pre-treatment system is almost always required. Typically, a multi-media filter would be used, often with a preceeding coagulator-clarifier. Even with particulates and colloids controlled, fouling of R.O. membranes can occur if heavy metals (Fe, Al, Cu, etc.) or oil and certain other organics are present in the feedwater. Such materials may be removed in the particulate/colloid pretreatment section by manipulation of pH, and sometimes addition of activated carbon treatment for organics. Often foulants cannot be removed completely, and resort is made to periodic cleaning of the R.O. with detergent/chelant solutions. Scaling, the precipitation of low solubility solutes on membrane surfaces, can be a serious problem in R.O. equipment. The most common scale formers are calcium carbonate, calcium sulfate, and silica. One obvious method of avoiding scale is to restrict operation such that the solubility limit of the scale former is not exceeded, and just that is done in many cases. In recent years, some increased tendency in that direction has been noted.

Solubility limits may be exceeded to a limited extent if a scale inhibitor is added, and this is a common practice. The limit of effectiveness of a scale inhibitor is often difficult to predict, but seldom exceeds twice the uninhibited concentration and is often lower. If operation beyond scale former solubility limits and the effective range of inhibitors is desired, resort is made to pretreatment system removal of one constituent of the scale former. Prevention of calcium carbonate scale is achieved by acid addition (necessary for other reasons as well) which converts carbonate ions to the soluble bicarbonate form. Reduction of calcium by softening will allow higher concentrations before reaching the calcium sulfate solubility limit. Similarly, silica may be removed along with calcium during softening.

It is apparent that, even for a relatively simple desalination R.O. application with common feedwaters, pretreatment system requirements are significant. If operation is desired beyond the solubility limits of scale formers such as calcium sulfate and silica, pretreatment requirements become much more extensive. The cost, both capital and operating, of such pretreatment systems can double system costs as shown in Figure 2 [taken from O'Neail, Kirchner and Day (3)]. The principles described above apply to wastewater applications of R.O. as well as the straight forward desalination applications. However, the magnitude of the problems is greatly increased with wastewaters.

Wastewaters tend to be high (very high in R.O. terms) in particulates and colloidal material. Wastewaters, particularly industrial wastewaters, usually contain some oil, organics of varying nature, and small-to-medium amounts of heavy metals. A majority of wastewaters are near saturation in calcium sulfate and silica - Figures 3 and 4.

In any case, saturation is usually reached in operation since high recovery (in excess of 90 percent) is desired to reduce reject disposal problems. Extensive pretreatment facilities are needed for R.O. to operate successfully on such feeds. Further, wastewaters almost always vary widely and rapidly in composition and characteristics. Figure 5 [Gianelli (4)] shows the variation with time of the silting index of a natural pond water as an example. All of these factors lead to greater-than-anticipated expense, operational difficulty and upsets not only in the pretreatment section but in the R.O. system itself. While some successful installations can be adduced, the general history of R.O. in high recovery wastewater applications is, at best, of mixed success.

Field testing of a new, patented (2) process approach to the prevention of scale precipitation and fouling in R.O. equipment is the subject of this paper.

Figure 4. Mine Water

Figure 5.

This process has been called "seeded R.O.," from the fact that seed crystals are deliberately introduced in the brine stream to induce preferential precipitation of scaling components on the seed. Since the slurry circulating in the R.O. apparatus carries in excess of 20,000 mg/l of fine seed crystals, the tubular R.O. configuration is used, although other configurations are under investigation.

Results of earlier laboratory testing were reported by O'Neail, Kirchner, and Day in 1982 (3). The feedwaters for these tests were:

- laboratory synthesized cooling tower blowdown

- A well-water blend, (OWRT Roswell Test Facility Plant Blend Number 3).

These test feedwaters were at saturation in calcium sulfate and silica. However, they did not exhibit the other characteristics of industrial wastewaters mentioned previously. Therefore, a site for field testing was sought which would possess the wastewater characteristics expected in a practical installation. An appropriate site and cooperating, owning organization was found in late 1982, and a five-element test unit was installed and started in May 1983.

All of the characteristics needed for a realistic test of an R.O. wastewater process are present at this site.

- The R.O. feed is a mine wastewater.
  - saturated in calcium sulfate
  - moderately high in silica
  - contains significant quantities of aluminum and iron, other heavy metals present
  - contains oil on occasion
  - other organics present in small amounts
  - particulates present in quantities to cause a murky appearance
  - temperature is 85°F to 90°F
  - variable in composition
- The location is overseas.
- Operation is by local personnel, inexperienced with R.O.
- Operation was day only, six days a week for the first three months.
- The R.O. elements are a new design not previously used for the "seeded" process.
- Recovery is 95 percent.

Two analyses of the raw mine water are shown; one taken in August 1983 (Figure 6), the other in February 1984 (Figure 7). A photograph of the raw mine water feed to the seeded R.O. unit is shown in Figure 8.

Before discussing the test results, a brief description of the process, the test unit, and the test protocols is in order. The process itself is quite simple in concept, although not quite so simple in practical application. As is well known, the activation energy for cystallization from solution varies with the surface presented to the saturated (or supersaturated) solution.

Figure 7.

Taking advantage of this fact, it has been found that, if a sufficiently large amount of "seed crystals" are present in a supersaturated or supersaturating solution, precipitation down to saturation will occur only on the "seed crystal" surfaces and not at all on other surfaces presenting to the supersaturated solution. Questions that must be decided for a particular application are:

- What material for "seed"?
- What quantity of "seed"?
- How to keep "seed" uniformly distributed?

In general, the "seed" material should be crystals of the material which will precipitate. However, it has been found that limited amounts of foreign precipitants can be "seeded" on certain "seed" crystals and scale formation by the foreign precipitant thereby prevented. Silica, for instance, can be "seeded" on calcium sulfate crystals (within limits) and silica scaling prevented.

The amount of seed depends, among other things, upon the nature of the precipitating material and its solubility, the rate of precipitation, and the size of the "seed" crystals. Slurry concentrations can range from 1 to 30 percent suspended solids. More detailed discussion is contained in the patent for the process, to which reference is made (2).

The matter of keeping the "seed" uniformly distributed, while a matter of careful mechanical design, is of great importance to the success of the process. All the usual precautions exercised in handling slurries must be observed: avoid stagnant areas, maintain velocities, avoid obstructions, flow passages must be large relative to the largest crystals. For these reasons, the tubular R.O. configuration has been used to date for the "seeded R.O." process. Some variations of spiral configurations have been tried, unsuccessfully so far. Other configurations are under consideration.

The test unit was a skid-mounted assembly of up to six tubular R.O. elements in series with associated pumps, tanks, valves, chemical addition equipment, etc. The unit had been used for previous tests equipped with different R.O. elements. A photograph is shown in Figure 9, and a flow schematic in Figure 10. (The feed tank, pump and filter were bypassed early in the test.) Note that the flow schematic shows a recycle of the reject brine to the feed tank. This is done so that a 95 percent recovery can be attained with a small number of modules, while maintaining the minimum brine flow required in tubular elements - especially when handling a slurry. A hydroclone is used on the reject flow to reduce the suspended solids in the reject to equal the amount of solids precipitated. The remainder is recirculated to the system. Not long after system start-up, the feed tank, feed pump, and feed filter shown on the schematic were eliminated. Feed supply and chlorine addition were thereafter made to the recirculation sump.

Figure 10. Schematic Showing Seeded RO Test Unit

The R.O. elements used were obtained from local manufacturers in the overseas location. In many respects, they are a standard, approximately eight foot, tubular element containing 19 one-half inch tubes in series. These elements do use a unique proprietary tube support system. The membrane is a nominal 90 percent rejection cellulose acetate with conventional flux characteristics. These particular tubular R.O. elements had not previously been used for the "seeded R.O." process, although limited laboratory tests had been completed before overseas start-up.

The test protocol aimed in general to test the feasibility of the "seeded R.O." process to treat the calcium sulfate saturated mine water previously mentioned to a high recovery, preferably in excess of 90 percent. To that end, evaluation factors were concentration factor (recovery), permeate flux, pressure drop, and permeate quality and rejection. The variation of the factors with time is, of course, important. To these objective factors were added the more subjective factors of reliability, adaptability to changing conditions, and operability by local operators.

The test procedure finally adapted was rather simple. A baseline element performance on two percent sodium chloride solution was first established. A rerun of this baseline is intended at the conclusion of the test to establish comparative data on module performance. At the beginning of the test, all modules met their specified flux and rejection. The test unit was then placed in a concentrating mode (recycling all

reject) with one R.O. element installed, and mine water feed started.

At this time seeding of the recirculation sump with gypsum "seed crystals" was necessary since no level of "seed" had built up in the system by natural precipitation. When the desired reject concentration representing 95 percent recovery (20 concentration factors) was reached, the unit was switched to a normal operating mode wherein both permeate and reject are discharged. Due to the size of the recirculation sump, and the one-shift-a-day operation imposed by operator availability, the concentrating mode took about two weeks.

After reaching concentration, the normal operating mode was continued for about two weeks (96 hours) with the single R.O. element. This established that satisfactory non-scaling operation had been achieved, and served to further familiarize the operators with the equipment and procedures. Then R.O. elements were added one at a time until the applied pressure differential to the R.O. membrane was too low to be useful. For the equipment used and this feedwater, five elements in series was the limit.

About this time, the operator availability was improved and 24-hour-a-day, six-day-a-week operation was possible. Operation on that basis has continued and is continuing. About 2,600 hours have been accumulated on the high-time element.

At 95 percent recovery (20 concentration factors), the original feed of 3,000 mg/l total dissolved solids has been concentrated to a reject containing approximately 60,000 mg/l total solids. Of this, about 20,000 mg/l remains dissolved while about 40,000 mg/l is present as suspended solids having precipitated from solution. Figure 11 is a picture of the liquids in the recirculation sump, which is about 50,000 mg/l total solids since the recirculated reject is somewhat diluted by the incoming feed. This, of course, is the slurry circulating through the R.O. elements.

An analysis of the sump recirculation brine is shown in Figure 12. Note the presence of significant amounts of heavy metals, especially iron, aluminum, manganese and nickel. Incidentally, this analysis would indicate that, at the time of sampling, recovery was running closer to 90 percent than 95 percent. This analysis also illustrates the difficulty of precisely measuring concentrations in these concentrated solutions. The mass balances for sodium, magnesium, and chloride (all presumably non-precipitating) each yield different results for concentration factor. Figure 12 also gives an analysis of the permeate. The permeate is of good quality and quite suitable for mine reuse. An analysis of the precipitated solids is shown in Figure 13. As expected, the major constituent is calcium sulfate, apparently in the gypsum form.

Figure 13.

Note the presence of about five percent precipitated silicaceous material, as well as the presence of significant amounts of precipitated iron and aluminum. The 4.6 percent loss on ignition for the solids after initial drying at 105°C is probably due to loss of hydration water, although such loss is frequently due to the presence of organics.

By January 1984, calendar time for the field test was eight months. Accumulated running time was 2,600 hours. Downtime was due almost entirly to operator availability -- during the first months of the test, operation was only eight hours a day for this reason. Judged on both the subjective and objective criteria, the process and test unit performance has been satisfactory. Despite the difficult conditions and severe service described, the unit has operated, and continues to operate, with no evidence of scaling. No cleaning of the R.O. elements was performed from start-up in May 1983, until January 1984.

Mechanical problems have been relatively minor. The high pressure pump seals required replacement in January but have been otherwise free of troubles. This pump had seen considerable service in our laboratories before the start of the current test. The feed pump motor proved unreliable, and this whole section was bypassed early in the test. At first, some incidents of hose blow-off from the R.O. elements occurred. This was solved by a change of hose and hose fittings.

Some early incidents of membrane rupture in the R.O. elements caused concern that erosion of the membrane might be occurring. Inpection, however, showed no evidence of erosion. Instead, cracking of the membrane support structure was found. Change in the support element has solved this problem.

The more objective measures of performance (flux, pressure drop, rejection) are presented in Figures 14 to 24. As can be seen, rejection and pressure drop have remained essentially constant throughout the test. An unexplained period of higher pressure drop is seen for module 4 (Figure 23) from time 300 hours to 1,000 hours. From 1,000 hours to 2,600 hours, however, pressure drop for module 4 has remained constant at about the original value. The flux versus time plots (Figures 14 to 21) are of some interest. First, the short-time modules, 1A and 2A, are R.O. modules which were replaced due to the membrane rupture mentioned previously. The flux values shown are normalized to 25°C and 2,758 kPa (400 psi). Flux has remained stable since about test time 500 hours. Prior to that time, a pronounced drop in flux was experienced especially for the first elements in the string. The reason for this behavior is not clear at this time. Scaling is not the cause, since pressure drop remains constant, and elements removed and examined show no sign of scaling. Fouling by organics or heavy metal oxides might be a cause. If so, the reason for the stabilization after 500 hours is unclear. Further, in January 1984, one R.O. element was cleaned with detergent and citric acid with no significant change in performance. Investigation is continuing.

The described field test of the "seeded R.O." process is regarded as successful and encouraging. The test will continue until mid-1984. Design of units for commercial offerings is in progress.

February 1981

Seeded Reverse Osmosis Concept

SUMMARY

A demonstration of Resources Conservation Co's patented seeded reverse osmosis (RO) process was conducted at the Office of Water Research and Technology test facility in Roswell, New Mexico. This work was carried out under OWRT Contract No. 14-34-0001-0451.

Seeded RO is a process that enables an RO system to be operated at high recoveries on a feed water that is saturated or nearly saturated with calcium sulfate. This is accomplished by adding crystals to the feed. These crystals provide sites to which material may precipitate.

Three separate tests were conducted. These tests demonstrated the unique RO process. The seeded slurry test was preceeded and followed by sodium chloride (NaCl) baseline tests. These tests provided a performance standard and a means to detect any adverse effects of seeded operation.

The seeded test was operated for 760 hours. During most of this time the system operated on a feed that was close to saturation with calcium sulfate and concentrated it by a factor of 10. The only pretreatment used was 25 micron filtration, acidification and chlorination. The level of suspended solids circulating through the RO modules was 15,000 mg/l or more.

During the seeded test the product flowrate fluctuated between 0.60 and 0.65 gpm. This is slightly higher than the product flowrate that is predicted for the water and operating conditions used.

The rejection began at 81% and decreased to 74% where it appeared to level off toward the end of the test. This rejection is lower than expected. It is felt that both the low rejection and high product flowrate is a result of normal performance decline since the modules have experienced a variety of previous service. The decrease in rejection over the course of the test is postulated as an indication that the system was in a dynamic state and finally reached steady state near the end of the test.

The module pressure drop was constant or decreased slightly during the test. There was no indication of any scaling or fouling.

The initial and final NaCl tests were run for approximately 44 hours preceeding and following the seeded test. There was an increase in product flowrate and a decrease in rejection from the initial to the final NaCl test. It is believed this was also a result of membrane performance decline, although further work may be warranted to explore the change in performance.

1.0 INTRODUCTION AND BACKGROUND

This report describes the test work performed by Resources Conservation Co. (RCC) under contract to the Office of Water Research and Technology. The overall objective was to demonstrate RCC's seeded reverse osmosis (RO) process.

Seeded RO describes a process conceived by RCC to allow RO systems to operate at a high recovery without the normally required pretreatment. A major operating limitation for conventional RO systems is the requirement that the solubility limit of any dissolved species must not be exceeded at any point in the system. When this happens the membrane is likely to become scaled as material precipitates on it. This results in decreased membrane permeability and increased pressure loss. Species commonly encountered which present this problem are calcium sulfate, silica and sometimes calcium carbonate.

In order to operate at recoveries where scaling by slightly soluble material may be a problem, conventional RO systems include equipment to pretreat the feed water. Pretreatment is aimed at either reducing the concentration of the dissolved species or inhibiting its precipitation. Common techniques to accomplish this are: lime, lime-soda and sodium zeolite softening, pH adjustment and sodium hexametaphosphate (SHMP) addition. These increase both the cost and complexity of the system.

A seeded RO system may be operated at recoveries exceeding 90% with minimal pretreatment. This is accomplished by adding seed crystals to the feed to the RO system. These crystals provide sites where the material may precipitate, rather than on the membrane. It should be mentioned that once the seed level is established, it is not necessary to add additional seed. As the

dissolved solids precipitate, additional seed crystals solids are formed. A portion of this material may be recovered from the reject and recycled to the feed to maintain the seed level. Tubular RO modules have been selected for use in this process because they provide an unobstructed flow path for the seed suspension.

RCC has been developing the seeded RO process since mid-1977. The project began with preliminary economic and technicial evaluations and has progressed through laboratory experiments and more detailed studies. Much of the early work has been described in a paper presented at the 1978 IDEA conference [1]. In June of 1980 RCC was assigned a patent covering the seeded RO process.[2]

One of the limitations of laboratory testing has been the use of synthetic feed water. Because of the volume required, it was not feasible to transport water from various locations to the laboratory. In order to have the ability to demonstrate the seeded RO process on real water at various locations, RCC fabricated a portable seeded RO test unit. At the end of 1979 RCC submitted a proposal to the OWRT entitled, "High Recovery Seed Slurry Demonstration for Desalting Water Saturated in Calcium Sulfate" and proposed operating the portable test unit at the OWRT test facility in Roswell, New Mexico. This proposal was accepted and on-site activities began on September 9, 1980.

2.0 OBJECTIVES

The primary objective of this program has been to demonstrate the feasibility of the seeded RO process for operation at high recovery on a water saturated with calcium sulfate. Minimal pretreatment would be used during the test. In addition, the operation of the test unit at the Roswell facility marks the

first time the seeded RO process has been run using a real feedwater rather than a laboratory synthesized simulation of actual existing waters.

3.0 APPARATUS

The demonstration program was conducted using RCC's portable seeded RO test unit. This is a skid mounted unit containing the RO modules, pumps, tanks and other equipment. It is shown schematically in Figure 1. Feedwater is supplied to the unit from a pressurized source through a float-actuated valve located at the feed tank. This valve maintains a constant level in the feed tank. Chlorine in the form of sodium hypochlorite is injected in the feed tank to prevent the growth of biological material. A propeller-type mixer is mounted on the tank to provide mixing.

Water is pumped from the feed tank by the feed pump. Some of the water is recirculated back to the feed tank while the rest is pumped through a cartridge filter. This is a string-wound filter rated at 25 microns. From the filter the water is fed into the recirculation sump. It enters through a float-actuated valve that keeps a constant level in the recirculation sump. Acid is added to the sump to prevent membrane hydrolysis and carbonate scaling. A propeller-type mixer is provided to mix the acid and also keep the seed particles in suspension. Since much of the liquid is recirculated an appreciable amount of heat is added to the system from the pumps. To prevent overheating, a cooling coil is located in the recirculation sump. Cooling water is circulated through this coil to remove heat from the system.

Figure 1. Schematic of Portable Seeded RO Test Unit

The recirculation pump draws water from the recirculation sump. A portion of the discharge is recirculated back to the sump. This aids in keeping the seed particles suspended. The remainder of the discharge is fed to the high-pressure pump. This is a multi-stage centrifugal pump and it provides the required pressure feed to the modules. A portion of the discharge from the high-pressure pump is directed back to the recirculation sump through a bypass valve and a shell-and-tube heat exchanger. This provides additional heat removal capacity. The rest of the discharge from the high-pressure pump feeds the tubular RO modules.

The modules used in this test are Osmotik Type 520 RO modules manufactured by Fluid Systems Division of UOP Inc. Appendix A contains product data relating to these modules. A series arrangement of four modules was used. Sample valves are provided to collect samples from the feed, reject and product from each module. Also, pressure gauges are located upstream and downstream from each module to measure feed and reject pressures. The product from each module is collected in a manifold. The total product then flows to a 3-way valve. With this valve the product may be directed to either the drain or back to the recirculation sump.

The reject stream from the final module flows through the reject throttling valve. By adjusting this valve in coordination with the bypass valve the system feed pressure and overall reject flowrate may be set at the desired values. The overall reject flowrate is measured using a magnetic flowmeter located in the reject line, just downstream of the reject throttling valve. The reject waste leaves the system through the reject waste valve. This is a timer-actuated valve and the reject flowrate is adjusted by changing the frequency and duration that the valve is actuated. The rest of the reject from the final module is recirculated back to the recirculation sump.

Figure 2 shows a photograph of the test unit.

The unit was packaged and shipped to the OWRT test facility in Roswell, New Mexico. It was moved into a test bay and the following connections were made:

1. Feed. The feed used was a blend of brackish well water and city water. It is a standard blend used at the plant and is designated Blend No. 3. The water had passed through an activated carbon filter and a manganese green sand filter before reaching the feed tank. A typical analysis of this water is presented in Figure 3.

2. Reject waste. Connected to plant drain.

3. Product. Connected to plant drain.

4. Cooling water. Reject brine from another test system was used for cooling water. City water was used as a back-up.

5. Electrical power. A 100 amp service was provided.

Another seeded RO test unit used by RCC in extensive long term tests is shown in Figure 4. The unit is located in RCC's test facility in Seattle, Washington. The modules shown have completed nine months of continuous operation with no change in flux or rejection.

Sodium (Na^+)	710 mg/l

4.0 PROCEDURE

This demonstration program was performed in three phases.

1. Initial sodium chloride (NaCl) test.
2. Seed slurry test.
3. Final NaCl Test.

4.1 Initial NaCl Test

The purpose of the initial NaCl test was to establish a performance baseline for the test unit under specific operating conditions. At the completion of the seeded slurry test there operating conditions would be repeated in the final NaCl test. By comparing the performance obtained in the two tests under the same operating conditions, any effects of the seed slurry operation could be detected.

The initial NaCl test was run with the unit in the complete recycle mode. In this mode the unit was operated in a closed loop by returning all of the product and reject to recirculation sump. This was accomplished by positioning the 3-way valve in the product line so that all of the product was directed back to the sump. Also, the reject waste valve was not put into operation.

The sump was loaded with a 2,000 mg/l NaCl solution. This was created by filling the sump with RO product water, procured from another test system, and adding 4.19 lb of NaCl. The unit was initially operated at low pressure, using only the recirculation pump, for 5 minutes. The product and reject streams were discharged to drain in order to purge the storage solution from the modules.

Figure 4: Photograph of Seeded RO Bench Model Test Unit, located at RCC Test Facility in Seattle

The unit was then put in the complete recycle mode and the high pressure pump was started. The feed pressure was adjusted to 500 psi and the reject flow was adjusted to 3.0 gpm. This was done by simultaneously adjusting the reject throttling valve and the by-pass valve. Figure 5 summarizes the operating conditions during both the initial and final NaCl tests.

The test was run for approximately 2 days. During this period 5 sets of data were collected at similar intervals. Figure 6 shows the data that was collected.

4.2 Seeded Test

For the seeded test the unit was switched from the complete recycle mode first to the concentrating mode and later to the normal mode. In the concentrating mode the valves were positioned so that the product was discharged to the drain and all of the reject was returned to the recirculation sump. This was achieved by positioning the 3-way valve in the product line so that the product was discharged from the system. Also, in this mode the reject waste was closed at all times. With the unit operating in this configuration the liquid in the recirculation sump became more concentrated as the system was operated.

Before starting the unit, an initial seed level was established in the recirculation sump. This was done by adding 75 lbs. of pharmaceutical grade terra alba (calcium sulfate) to the sump. This produced a suspended solids concentration of 20,000 mg/l. During the addition of the terra alba the mixer and recirculation pump were operated to mix the terra alba and keep it in suspension. The block valve in the high-pressure pump suction line was closed to prevent the slurry from being fed to the modules during the mixing process.

Figure 5. Summary of Operating Conditions for Initial and Final NaCl Tests

Feed Solution	2,000 mg/l NaCl
Feed Pressure	500 psi
Reject Flowrate	3.0 gpm
Feed pH	4.5 - 5.5
Feed Chlorine	0.2 - 0.5 mg/l

Figure 6. Data Collected During Initial and Final NaCl Tests

Operating Data:

- Elapsed time from start of test
- Feed pH
- Feed Chlorine
- Feed Temperature
- Feed Pressure
- Feed Conductivity
- Reject Flowrate

Performance Data:

- Product Flowrate
- Product Conductivity
- Module Pressure Drop

With the terra alba well mixed in the recirculation sump the unit was put into operation. The block valve in the high-pressure pump suction line was opened and the pump was started. The feed pressure was adjusted to 500 psi and the reject flow was adjusted to 500 psi and the reject flow is adjusted to 3.0 gpm. This was done by simultaneously adjusting the reject throttling valve and the by-pass valve. Figure 7 summarizes the operating conditions during the seeded test.

The unit was operated in the concentrating mode until the liquid had been concentrated 10 times, on a volume basis. The degree of concentration was determined by monitoring the quantity of water fed into the unit using the water meter in the feed line. When a volume of water equal to 10 times the system volume had been fed into the unit, the water had been concentrated 10 times. When this point was reached the unit was put in the normal mode.

In the normal mode the reject waste valve was put into operation and a portion of the reject was discharged. The amount to be discharged depends on the desired concentration factor. The concentration factor, CF, is the degree of concentration of the reject stream and is calculated using the expression,

$$CF = \frac{\text{Feed flowrate}}{\text{Reject waste flowrate}}$$

The unit was operated at a CF of 10. Since the feed flowrate could be measured and the CF was known, this reject waste flowrate could be calculated. The timer actuating the reject waste valve was adjusted to give the required reject waste flowrate.

During the seeded test a simulated seed recycle system was used to maintain a seed level. It was not practical to install a system to recover seed from the waste stream on a test system

Figure 7. Summary of Operating Conditions For Seeded Test

Feed Solution	Plant Blend No. 3
Feed Pressure	500 psi
Feed pH	4.5 - 5.5
Feed Chlorine	0.2 - 0.5 mg/l

such as this. Instead, 12 lbs. of terra alba were added to the recirculation sump approximately every 12 hours. This simulated the operation of a seed recycle system operating under similar conditions.

The unit continued operating in the normal mode for a month. During this time operating and performance data were collected twice daily. Figure 8 summarizes the data collected during the seeded test.

At the completion of the seeded test the unit was shut down and the sump drained. After this the final NaCl test was run.

4.3 Final NaCl Test

This test was conducted in the same manner as the initial NaCl test. The identical data were also collected.

5.0 RESULTS

The initial NaCl test was carried out over a 46 hour period. This was followed by the seeded test which was terminated after 760 hours. During this test the unit was in continuous operation except for a 5-hour period after an interruption in the electrical supply to the plant. The final NaCl test followed the seeded test and lasted for approximately 43 hours.

5.1 Seeded Slurry Test

The performance of the test unit was evaluated on the basis of the following calculated parameters:

Operating Data:

- Elapsed time from start of test
- Feed pH
- Feed chlorine
- Feed temperature
- Feed pressure
- Feed conductivity
- Feed TDS
- Feed SS
- Reject flowrate
- Reject TDS
- Reject SS

Performance Data:

- Product flowrate
- Product conductivity
- Module pressure drop

Figure 8. Data Collected During Seed Test

a) Recovery
b) Product flowrate, corrected to 77°F
c) Rejection
d) Pressure drop (Delta P)

These were determined from the data collected during the test, using the equations given below.

$$\text{Recovery} = \frac{\text{Product Flowrate}}{(\text{Product Flowrate} + \text{Reject Flowrate})}$$

$$\text{Rejection} = \frac{\text{Feed Conductivity @ Module 1}}{(1 - \text{Reject Conductivity @ Module 4})}$$

$$\text{Pressure Drop} = (\text{Feed Pressure @ Module 1}) - (\text{Reject Pressure @ Module 4})$$

The product flowrate was measured directly and was corrected to a reference temperature of 77°F. This was done using the expression,

$$Q_{77} = Q_T \, 1.013^{(77-T)}$$

Where: Q_{77} = product flowrate corrected to 77°F, gpm
Q_T = measured product flowrate, gpm
T = Actual temperature, °F

This expression represents an average of the temperature correction factors used by different membrane manufacturers and is considered reasonable at 77 ± 18°F [3].

Figure 10 shows the recovery of the test unit as a function of time. Since the product flowrate was equal to the feed flowrate during the concentrating stage, the recovery was 100% during this stage. Once the water in the recirculation sump had become

	Average	Minimum	Maximum
Feed Temperature, ^{o}F	85	81	88
Feed pH	5.0	4.0	7.0
Feed Chlorine, mg/l	.35	0.0	1.0
Feed TDS, mg/l	4,670	4,500	4,900

Figure 9. Feedwater Conditions During Seed Test

Figure 10. Plot of Recovery vs. Time for Seeded Slurry Test

concentrated by a factor of 10 the waste valve was put into operation and the reject waste flowrate was adjusted to maintain a recovery of 90% or greater. Figure 10 shows that this was accomplished during the seed slurry test.

Figure 11 shows a plot of product flowrate, corrected to 77°F, as a function of time. This shows that the product flowrate was about 0.65 gpm at the beginning of the test and dropped to slightly less than 0.55 gpm during the concentrating stage. This decrease is expected since the TDS of the recirculation sump is constantly increasing during this stage. This decreases the effective feed pressure as a result of the higher osmotic pressure.

After the unit was switched from the concentrating to the normal mode, the product flowrate increased and throughout the rest of the test fluctuated between 0.60 and 0.65 gpm. Calculations based on manufacturer's data indicate the expected product flowrate for four modules in series operating under these same conditions is approximately 0.55 gpm. The higher measured product flowrate is a symptom of brine-to-product leaks. This is not completely unexpected. These modules were purchased in 1978 and have been the subject of several tests in RCC's laboratory. It is felt that the high product flowrate is a result of normal membrane deterioration.

A plot of rejection vs. time is shown in Figure 12. This shows the rejection at the start of the test was about 81%. During the test this declined steadily to 74% where it appeared to level off. This rejection is lower than expected for these modules. However, it is felt that this may also be attributed to membrane deterioration since both high product flow and low rejection are a symptom of brine-to-product leaks.

Figure 11. Plot of Product Flowrate vs. Time for Seeded Slurry Test

Figure 12. Plot of Rejection vs. Time for Seeded Slurry Test

Initially the decline in rejection, which amounted to 8.6% in less than 30 days, was viewed as a possible indication of module scaling/fouling. However, the other usual indicators were not present. The product flowrate fluctuated, but did not show a steady decrease.

The module pressure drop was steady or declined slightly. Also, the rejection did seem to reach a constant level toward the end of the seed slurry test.

It is postulated that the decline in rejection is an indication that the system was in a dynamic state. It is recognized that RO membranes reject trivalent and divalent ions better than monovalent ions. During the concentrating stage all of the product is discharged and all of the reject is returned to the recirculation sump. Thus the relative proportion of multivalent ions in the sump becomes greater than that of the feed. When the unit is switched from the concentrating to the normal mode the multivalent ions begin leaving the system at a greater rate. As a result, the concentration of the multivalent ions in the sump drops which causes a decrease in the rejection. It appears that the system had reached equilibrium toward the end of the test.

Figure 13 is a plot of module pressure drop as a function of time. This shows that the pressure drop fluctuated and experienced a slight decline toward the end of the test. If the system had experienced fouling as a result of operating on a slurry of seed crystals, an increasing pressure drop would have been expected. Since this was not the case it can be concluded that this type of fouling did not occur.

Figure 13. Plot of Pressure Drop vs. Time for Seeded Slurry Test

The results of the seeded test demonstrate that the seeded RO process may enable an RO system to be operated at a recovery that would not normally be possible. Scaling by precipitating species is not a problem. Also, the modules are not subject to fouling by the suspended seed crystals.

5.2 Initial and Final NaCl Tests

A comparison of the results from the initial and final NaCl test is shown in Figure 14. The operating data indicate that the tests were carried out under similar operating conditions. The performance data shows an increase in product flowrate and a decrease in rejection from the initial to the final NaCl test. The average product flowrate was 11% higher during the final NaCl test than during the initial NaCl test. The average rejection decreased 9.2% from the initial to the final NaCl test.

It is possible the different performance in the 2 tests may be caused by normal membrane deterioration. It is also possible this may be an effect of operation with the seed crystals. However, similar modules have been operated continuously for up to nine months in RCC's laboratory with no evidence of any such effects. It is felt that this is an area that should be explored further, possibly using fresh modules in a long term test.

5.3 Chemical Analyses

Samples of feedwater, permeate, reject, and sump concentrate were taken once a week to be analyzed on site in the OWRT, Roswell laboratory. Chemical analyses will allow direct derivation of the rejections for the different ions. This would resolve whether the decrease in rejection during the seeded slurry test

was indeed due to a relative increase of monovalent ions with respect to divalent ions in the sump concentrate. RCC will attempt to publish the results of these analyses when we receive them.

6.0 CONCLUSIONS

The primary objective of this test effort, that of demonstrating the feasibility of the seed RO process, has been achieved. The seeded test unit was operated for over a month at a recovery of 90% or more on a water that is nearly saturated with calcium sulfate. An analysis of the feed using the correlations of Marshall and Slusher (4) indicates that the water becomes saturated with calcium sulfate at a recovery of approximately 75%. There was no indication of fouling or scaling during the test.

ACHIEVING HIGH RECOVERY FROM BRACKISH WATER WITH SEEDED REVERSE OSMOSIS SYSTEMS

OTTO E. KIRCHNER and TERRY M. O'NEAIL

Resources Conservation Co.
Seattle, Washington, U.S.A.

Since 1973 the use of reverse osmosis to reduce the salinity of feedwater has increased tenfold. The applications include the production of ultra-pure water for the manufacture of electronics, the treatment of brackish ground water for potable use and the desalination of seawater. As operational experience accumulates there is increasing confidence that reverse osmosis will perform satisfactorily so long as proper pretreatment is provided. Proper pretreatment permits the R.O. system to realize its potential performance and extends its useful lifetime. In many instances, however, pretreatment accounts for a significant portion of the capital and operating cost of the overall system and in addition, may make major demands upon the workload and skills of the plant operator. For these reasons an R.O. system operating free of pretreatment represents a highly desirable goal and major steps toward reducing the requirements for pretreatment could provide significant benefits in decreased R.O. system complexity and cost. The purpose of this paper is to describe certain development activities currently underway at Resources Conservation Co. in Seattle, Washington, U.S.A. with a patented reverse osmosis concept for reducing the pretreatment requirements of R.O. systems without compromising the permeate recovery of these systems.

The area of application considered here is the use of reverse osmosis to reduce the salinity of either surface water or ground water where softening is a prerequisite to achieving adequate recovery.

Figure 1 shows the relationship between percent recovery and the salinity of the R.O. reject for various levels of recovery, using, as an example, the feedwater at the Yuma Desalting Test Site in Yuma, Arizona, U.S.A. The feedwater has an initial salinity of approximately 3,000 parts per million (ppm) total dissolved solids (TDS). If this water is treated by an R.O. system various levels of recovery will result in reject streams having salinities as shown on the ordinate of Figure 1. For the water chemistry of this feedwater the hardness is such that if no softening were undertaken the R.O. recovery of permeate from this stream would be limited to approximately 55% or 60%. Use of cold lime softening will allow the recovery to be increased to 85%. Complete softening, using lime-soda, would permit complete recovery to the osmotic pressure limit shown on Figure 1. So it can be seen for this water that use of R.O. without softening significantly penalizes the recovery potential of the reverse osmosis.

Figure 1. Effect of Softening on Reverse Osmosis Recovery

The operating and capital cost penalty for the softening pretreatment is indicated in Figure 2. These two bars represent the capital cost and operating cost respectively of an R.O. system. On each bar the value of 1.0 corresponds to the cost of the R.O. system itself, exclusive of pretreatment costs. The top of the bar indicates the total system cost including pretreatment. The magnitude of the pretreatment portion of the two bars, both with respect to capital cost and operating cost is an indication of the potential savings to be realized if softening and other pretreatment could be eliminated.

Figure 2. Impact of Pretreatment on Total Reverse Osmosis Costs

In searching for means to eliminate the requirement for pretreatment Resources Conservation Co. turned to another water treatment process with which it has become identified during the past ten years. This is the recovery of pure water from a brackish stream saturated with calcium sulfate, silica, or both through the use of the vertical tube, falling film, vapor compression evaporator. Resources Conservation Co. has been the leader in producing commercial evaporator systems for the purpose of achieving very high recoveries (90% to 99%) from brackish streams saturated with scaling components such as those mentioned above. RCC committed to a test program to determine if the same approach used to achieve high recoveries without scaling in its evaporators might also be applicable to achieving high recoveries without scaling in a reverse osmosis system with a feedwater saturated with scaling minerals such as calcium sulfate and silica.

The process used by RCC in its evaporators to avoid scaling is schematically demonstrated in Figure 3. The left-hand figure illustrates the vertical orientation of the tube-in-shell heat exchanger with its large number of vertical tubes. The incoming hot feed is mixed with the concentrate slurry in the conical sump and is continuously recirculated to the top of the evaporator. There it is distributed to the inside wall of each tube as a thin film. The central portion of Figure 3 represents a magnification of just one of the many vertical tubes with its associated brine film. In this system the vertical tube transfers heat to the falling film causing a small fraction to vaporize. The vapor thus formed enters the compressor where it is compressed about 2 psi on the shell side of the evaporator. This pressure increase causes the condensation temperature of the steam to be raised about 6 degrees above the boiling point of the recirculating brine. As this steam gives up its heat of condensation it condenses on the shell side of the tubes and is collected in the product tank. The release of the heat of condensation causes more water to be evaporated from the brine inside the tube. The right hand portion of Figure 3 depicts the key to the evaporator's thermochemical operation. As water is evaporated inside the tubes the remaining brine film becomes supersaturated, and, typically, calcium sulfate and silica precipitate. The precipitating materials promote crystal growth on the seed rather than nucleation and deposition on the heat-transfer surfaces. This scale prevention mechanism, called preferential precipitation, has proven its capability to maintain clean, scale-free, heat-transfer surfaces.

Figure 3. Scale Prevention Mechanism

Calcium sulfate crystals are introduced only at system startup since the process is a self-perpetuating one with precipitating crystals providing deposition sites in turn for future crystals. Through this process RCC has been able to achieve very high recoveries of 95% to 99%, starting with a feedwater saturated with calcium sulfate or silica. The recovery limit for these applications is therefore not limited by the presence of calcium or silica nor is softening required. In many instances the concentrate or waste stream from this system will have a salinity of from 200,000 to 350,000 ppm total solids.

This then is the mechanism which has been evaluated for its application to reverse osmosis systems to determine the possibility of achieving high recoveries without pretreatment even in feed streams saturated with calcium sulfate or silica. Figure 4 shows this concept in its simplest form. The unsoftened feedwater which is at or near saturation is circulated as a slurry within an R.O. module. Due to the nature of the slurry, the confines of the brine-side flow channel should represent a relatively smooth hydraulic zone such as that provided in a tubular R.O. module configuration. During the passage along the membrane, permeate will pass through the membrane causing the saturated calcium sulfate in solution to exceed its saturation limits and to precipitate. As in the evaporator, instead of precipitating on the flow channel wall, thereby plugging or fouling the membrane, the precipitating calcium sulfate will attach itself to existing crystals suspended in the feed stream. Consequently at the end of the membrane zone the chemistry of

the reject brine will differ from the seawater chemistry as a result of two effects. The concentration of total solids (dissolved and suspended) at the end of the tube will be greater than the concentration of like quantities in the feed due to the extraction of permeate and, the concentration of suspended solids in the reject brine will be greater than that in the feed stream as a result of precipitated calcium sulfate and silica caused by the reduced volume of the reject stream.

Figure 4. Seeded Reverse Osmosis Concept

As the feed stream is exposed to more membrane (or as the flow channel becomes longer) the osmotic pressure increases due to the increase in the level of dissolved solids. Correspondingly, the operating pressure along the tube reduces due to hydraulic losses within the system so that the net driving force across the membrane continues to diminish as permeate is extracted from the system. This effect is shown in Figure 5 and presents identical limitations and considerations to those observed in conventional reverse osmosis systems.

Figure 5. Effect of Extraction and Hydraulic Losses on Effective Pressure

The above discussion summarizes the idealized behavior of a "Seeded R.O." system. Following is a review of the testing that has been accomplished and a brief summary of the test results to date. The subsequent paragraphs include identification of some of the future work and the approximate timetable to which RCC is working.

Following the conception of the seeded R.O., an early activity involved a preliminary analysis of the economic potential associated with eliminating pretreatment of the feedwater to an R.O. system. That study, which was undertaken in 1977, indicated that further investigative and developmental efforts were warranted.

Actual testing commenced in March, 1978 using a one half-inch diameter cellulose acetate, tubular R.O. membrane. The modules employed were standard "off-the-shelf" tubular modules marketed by one of the major U.S. reverse osmosis equipment suppliers. A standard module contained about one hundred twenty-eight feet of this tubular membrane packaged into a module approximately four inches in diameter, seven and a half feet long. A series of tests, each about one week in duration, were undertaken to determine membrane performance using a feedwater seeded with calcium sulfate crystals. The particular water used in the tests was one familiar to RCC from some previous evaporator work in the State of Utah, U.S.A. The chemistry of this water is shown in Figure 6. The water seemed to be a good test stream because it is saturated with calcium sulfate, based on the predictions and correlations of Marshall and Slusher, and its inherent osmotic pressure is sufficiently low to permit relatively high recoveries. The purpose of these tests was to determine if the R.O. system could extract permeate from this unsoftened feed stream without scaling and, if so, what the limits of concentration might be.

	mg/l (as ion)
Sodium	106
Calcium	540
Magnesium	260
Chloride	58
Bicarbonate	0
Carbonate	0
Sulfate	2,467
Silica	60
Total dissolved solids	3,491
pH	5.5

Note: This water is saturated with $CaSO_4$.

Figure 6. Utah Water Chemistry (Acidified)

A schematic of the test system is shown in [illegible] feed is brought to a reservoir where it is mixed with reject brine [illegible] recycled from the R.O. module. The reject brine is a concentrated slurry containing calcium sulfate and silica in suspension, so it is necessary to agitate the feed tank to keep the suspended solids from settling. The feed proceeds to the high pressure pump and through the R.O. module. The permeate leaves the system and the reject brine is divided into two streams - a waste stream and recycled brine which is returned to the reservoir. The waste brine stream is throttled such that the system operation is controlled at the desired concentration factor. The reservoir was conditioned with an original charge of calcium sulfate crystals prior to start-up.

Figure 7. Test System Schematic

If a single pass through the membrane were desired, all the reject would be directed to the waste stream. However, the extraction of permeate on a once through pass employing a single module is only several percent of the feed volume. Overall recovery of the system is increased with the waste valve partially closed, causing a portion of the reject to be recirculated thereby increasing the overall system concentration capability. The feed rate to the reservoir is reduced as the recycle fraction is increased to maintain a constant feed tank level. Consequently, with the reduced feed rate the brine is recycled several times achieving a higher salinity in the reject and therefore an increased recovery of permeate. Concentration factors as high as 18 were achieved in the highest concentration tests. This is equivalent to a permeate recovery in excess of 94 percent. More importantly, this recovery was achieved in the absence of pretreatment and without scaling in the membrane module or elsewhere in the system. Logically, the raw feed was treated with a small amount of sulfuric acid to minimize the rate of hydrolysis of the cellulose acetate membrane.

Figure 8 presents the membrane performance achieved during the maximum concentration test series. The data reveals the typical and expected increase in rejection with increasing flux.

Figure 8. Membrane Performance - Seeded Reverse Osmosis

Figure 9 is a photographic view of one of the three test units employed in the Seeded Reverse Osmosis investigations. The tubular modules are visible in the left foreground and the reservoir with its mixer is seen in the right rear of the photograph.

Figure 9. Seeded Reverse Osmosis Test Apparatus

Figure 10 presents a time-span display of the significant events during the Seeded Reverse Osmosis program. The preliminary analysis of the economic potential also included studies pertaining to the various reverse osmosis module configurations and suppliers. The first test unit was erected and checked out in late 1977 and testing commenced in early 1978.

Figure 10. Seeded Reverse Osmosis Development Plan

Seeding feasibility tests in early 1978 demonstrated the preferential precipitation mechanism in a membrane separation process.

The testing activities for the following 10 month period were directed to evaluating and defining what were considered to be some of the process variables. The test conditions employed during the prior seeding feasibility tests were intentionally conservative in order to avoid confusing a process optimization malfunction with a preferential precipitation mechanism problem. One of the process variables studied was that of operating at increasing recovery or higher concentration factors. It was apparent the proposed Seeded Reverse Osmosis process would have only limited applicability if it were not functional up to the osmotic pressure limitations of conventional reverse osmosis. These tests were conducted using the Utah water (Figure 6) and were conducted up to about 18 concentration factors. At that point the total solids in the reject brine was about 60,000 Mg/l. Higher concentrations could have been attempted, but other process variables appeared more important during those early stages than extending the demonstrated 94 percent recovery.

The investigations were conducted very slowly from a time standpoint as evidenced by the appreciable time periods involved in each test. This cautious approach was necessary since it is well documented that many failures in membrane separation processes are extremely gradual in developing and not readily obvious to casual scrutiny.

Two other test units were installed and checked out before they were dedicated to evaluating other process parameters. One unit was employed to establish slurry velocity (Reynolds Number) criteria for a calcium sulfate laden brine in a one half inch tubular module. With the Reynolds Number tests a range of stream velocities through the module were studied. Minimum velocities were key to reducing pumping energy and increasing permeate extraction rates. A minimum velocity must be sufficient to maintain the feed slurry in suspension as it proceeds through the module and must minimize the concentration polarization layer.

By early 1979, the feasibility tests and parametric studies were sufficiently encouraging to warrant a two-pronged effort. The tests were continued with emphasis on membrane life characteristics, alternate membrane materials and alternate module configurations, while a parallel effort was directed toward preliminary design studies for both a pilot plant and full-size plant installations. By the end of the summer of 1979 a continuous steady state 6-month test had been completed on the Utah water at 90 percent recovery. That test is currently being extended for an additional 6 months.

Other membrane materials which have been evaluated for slurry operation include both polyamide and PBIL formulations. Currently a majority of the testing has been conducted using a cellulose acetate membrane but results would indicate other membranes are compatible with the Seeded R.O. process. Although most of the testing reported herein pertains to results from the standard tubular module configuration, several other module configurations are currently being evaluated.

The pilot plant program anticipates a test on an actual raw water in early 1980. Several alternative sites are being considered and discussions are underway with the appropriate client personnel. Based on the assumption that the pilot tests and the economic potential are encouraging RCC is planning to offer full size systems by late 1980.

Figure 11 summarizes the status of various test programs at this time. It is felt the concept of using seed slurry and preferential precipitation to avoid calcium sulfate scaling in an R.O. membrane has been verified. Tests to determine the limits of concentration factor have been completed and those results indicate that recoveries are possible up to the operating limits imposed by osmotic pressure restrictions. Flux tests and membrane per-

formance tests have been conducted. Tests to determine the channel size required to avoid plugging have been completed in conjunction with determinations of minimum velocity requirements for maintaining the slurry in uniform suspension. The susceptibility of pumps and membranes to erosion have been explored through periodic inspections of actual operating test equipment. Testing to evaluate alternate cleaning approaches is being planned and, as discussed earlier, the pilot plant is being designed.

Investigation	Status
Slurry process	Verified
Concentration factor - low of 1.2X to high of 18X	Complete
Brine velocities	Complete
Flux and membrane performance verification	Complete
Open flow channel requirements	Complete
Pump erosion (multi-stage)	Complete
Membrane erosion and life tests	Continuing
Hi extraction tests	Complete
Cleaning	In planning
On-site pilot demo	In planning

Figure 11. Seeded Reverse Osmosis Test Status

In summary this paper has discussed development work currently underway at Resources Conservation Co. on a unique R.O. concept. This concept, if successful, will permit high recovery without pretreatment of feedwaters saturated with calcium sulfate or silica. Testing to verify this approach has been accomplished using a tubular reverse osmosis module. Testing has also been extended to include coverage of several major design parameters such as extraction rate, stream velocity, concentration factor and operating pressure. Design effort has been initiated on a pilot plant with the objective of commencing pilot plant tests early in 1980.

REVERSE OSMOSIS PRINCIPLES

Osmosis is the phenomena by which a semi-permeable membrane allows the passage of the solvent (usually water) while it restricts the passage of solute particles which are also termed dissolved solids. (Fig A). The solvent travels through the membrane in both directions setting up a dynamic equilibrium in relation to the osmotic pressure of the solution. (Fig B.) The process of reverse osmosis involves the overcoming of the osmotic pressure of the solution which has the effect that the solvent is forced through the membrane in one direction only. (Fig C.) The solution becomes more concentrated as the solvent flows out through the membrane.

TUBULAR REVERSE OSMOSIS

Water is pumped at 30 - 50 bar inside the cellulose acetate tubular membrane with the effect that the pressure used not only overcomes the osmotic pressure of the solution, but forces enough permeate (pure water) through the membrane to derive the desired recovery (see diagram below). Between 70% and 90% of the feedwaters can be recovered, depending on what system configuration is used. Depending on the characteristics of the water, inorganic salts are rejected at the 90 - 95% level, while all bacteria, viruses, pyrogens and most organics are also rejected by the membrane.

INTRODUCTION TO MEMBRATEK

MEMBRATEK

Membratek is a division of Bintech (Pty) Ltd which in turn is a subsidiary of Bakke Industries Ltd, being part of the JSE listed Malbak Investment Group.

TYPE OF SYSTEM

Membratek offers a tubular Reverse Osmosis system with its primary function being the desalination of various types of water and industrial effluents, in fact all waters containing dissolved salts, organics, bacteria, viruses, etc.

SYSTEM CHARACTERISTICS

The robust characteristics of the tubular system include minimal pretreatment, reverse flow sponge ball cleaning which helps prevent fouling of the membrane, the solid cast module ends are leak-free due to the absence of traditional sealing methods, higher pressures can be accommodated by the system.

RESEARCH AND DEVELOPMENT

The ongoing R & D programme involves close ties with the Polymer Institute (University of Stellenbosch), the Water Research Commission and the National Institute for Water Research (CSIR).

MANUFACTURE

Low cost tubular modules and membranes are manufactured in their entirety at our Paarl factory. Complete plants are built by our engineering staff which are delivered and commissioned anywhere in Southern Africa.

MAIN ADVANTAGE

The system handles high fouling waters with relative ease.

THE MEMBRATEK MODULE

Based on an overseas concept, the Bakke Membratek System was modified for South African conditions and improved to the extent that it is now considered superior to imported conventional R.O. plants. The module design carries South African and EEC patents.

The R.O. modules have a 100% local content and were developed particularly for water with high fouling characteristics. Fouling agents such as organics, silica, iron and manganese can, to a large extent, be removed from the membrane surface by intermittent sponge ball flushing. The more exposed membrane surface facilitates cleaning, thereby minimizing the troublesome pretreatment stage needed in conventional R.O. plants.

Modules consist of cellulose acetate type membranes in tubes made up of polymer discs housed in aluminium, which reduces the cost of the tubular system to a level competitive with conventional spiral membrane systems. Each module contains 19 tubular membranes which are factory assembled and tested. Membranes are also replaced at the factory and old modules are exchanged for reconditioned ones as the need arises.

Pilot work on secondary sewage effluent indicates a membrane life of at least three years without any prefiltration for the R.O. stage. Total dissolved solids (TDS) reduction of 90% at a volume recovery of 75% have been obtained on a 12 month pilot run at Port Elizabeth Municipality. Comprehensive analysis of the product water indicates a quality better than SABS potable standards.

THE MEMBRATEK MODULE SPECIFICATION

1. SALT REJECTION	90 - 98% - 2 000 mg/l Na Cl 98 - 98% - 2 000 mg/l Na_2SO_4
2. MEMBRANE AREA	1,75 m^2 per module
3. INITIAL FLUX	700 - 1 000 l/m /d
4. DESIGN FLUX	500 - 600 l/m /d (at 40 bar 20 C and 1 000 mg/l Na Cl)
5. CLEANING	Reverse flow at 60 - 600 minute adjustable cycles using sponge balls for each row of modules
6. PRESSURE DROP	1 bar per module at 1m/sec velocity (7,6 l/m through 12,7 mm ø pipe x 1m/sec)
7. LINEAR VELOCITY	0,50 - 2,00 m/sec
8. MEMBRANE MATERIAL	Cellulose acetate (Tubular Membrane)
9. MEMBRANE PROPERTIES	pH range 3 - 6,5
10. RECOVERY RATES	± 70% at 5 000 TDS, - 85% at 1 000 TDS (Na Cl)
11. MEMBRANE LIFE	2 - 5 years depending on water quality

APPLICATIONS FOR TUBULAR REVERSE OSMOSIS

With the shortage of good quality water in most parts of the country, and the rising cost of water, it is becoming viable to purify and re-use various water supplies rather than discharge them. Listed hereunder are some of the desalination uses of tubular reverse osmosis:

1. High scaling waters can be desalinated to prevent scaling up of nozzle orifices, pump glands, pipes and other equipment that is in contact with water.
2. Effluent discharge can be re-used in industrial applications such as electroplating shops, etc.
3. Brackish water in remote areas can be purified well within potable standards.
4. Municipal feedwaters can be cleaned sufficiently for use in the electronics industry.
5. Because the membrane removes all bacteria, viruses, etc., it can be used for pharmaceutical water purification.
6. The system is also suited to purify secondary sewage effluents to both industrial and potable standards as tests by competent authorities have proved (the CSIR - NIWR and P.E. Municipality).
7. Ion exchange demineralisation is made more cost effective on waters with a high TDS. Up to a 97% saving on regenerant chemicals can be realised.
8. Systems that need high quality water such as boilers and heat exchangers, can be supplied by a Tubular Reverse Osmosis System, while at the same time the waters can be recycled through the system.

FACTS AND FIGURES — MEMBRATEK TRO

1. **The Difference between TRO and RO**
   There are two major differences between tubular reverse osmosis and the more commonly encountered spiral wrap or hollow fibre techniques. The first is the tubular system's ability to handle high fouling waters without fouling the membrane irreversably. The technology is best suited to difficult waters such as high hardness waters in systems where scaling creates problems. The other major difference between our technology and other membrane systems is the minimal amount of pretreatment our systems require. Because fouling is not a problem, only cartridge type coarse filtration is used in conjunction with acid dosing and chlorination if needed.

2. **Energy consumption**
   The only electrical energy used is for driving the pump motors. Very little is used for instrumentation and controls. The total consumption ranges between 1,5 - 3,0 kwh/m^3 of product water, depending on the feedwater quality and the size of the system.

3. **Membrane replacement cost**
   Membrane replacement costs between 10 and 20 cents per m^3 water produced depending on the membrane life which can vary between 2 and 5 years.

4. **Experience**
   Apart from laboratory types tests on various waters/effluents and our local (Pearl) pilot testing the following pilot tests have been performed (starting from the most recent):

Location	Water Type	Remarks
(a) Grootvlei (ESCOM)	Cooling Tower	Considerable reduction of hardness and TDS.
(b) Port Elizabeth	Secondary Sewage	Water produced to potable standards.
(c) ERPM	Acid Mine Water	Seeded slurry with high recoveries.
(d) Bellville	Secondary Sewage	Water produced to potable standards.
(e) Vaal Reefs	Vaal River water	High quality process water obtained.

Brackish water with a high TDS (3000 - 5000 TDS in the case of the plant purchased by the Department of Community Development) can be desalted by our systems.

SCOPE OF SUPPLY

Apart from the hardware listed hereunder the following are also part of the scope of supply:

- Delivery and insurance.
- Installation
- Commissioning
- Training of supervisory staff and operatives.

1. **Instrumentation and Control**
   Pressure is controlled at the feed water inlet for low pressure while high pressure controllers are located after the pumps and on the outlet stream. Temperature measurement and control along with pH measurement and control also protect the membranes from out of specification feed waters. Along with high permeate conductivity measurements and excessive power consumption all the above parameters if exceeded (or out of specification) cause the motors driving the pumps to "trip-out". The permeate conductivity measurement includes a feed conductivity measurement and a percentage rejection measurement for comparing data. Also included are flow meters on feed, product and reject streams. On some systems both rotameters and digital readout flowmeters are used depending on the degree of sophistication of the particular plant. A spongeball reverse flow system is included which incorporates a timer that can be set to activate the reverse flow mechanism, as the cleaning cycle demands.

2. **Power**
   Small plant utilise either 250v or 380v while larger plants normally run on 380v or 550v.

3. **Cleaning In Process**
   A C.I.P. tank (sometimes also doubling as a feed tank) is included. Cleaning is done approximately once per fortnight and involves circulating a citric acid and/or detergent mixture through the system for 2 - 4 hours, and then returning the mixture to the C.I.P. tank if it is separate from the feed tank.

4. **Pumps and Motors**
   On small plants positive displacement pumps are used which require a 0,8 to 2 bar feed. Larger plants use multistage centrifugal and/or positive displacement pumps depending on the design configuration. Pumps are either belt drive or direct drive, the motor also being supplied.

5. **Plant Configuration**
   The mechanical part of the plant consists of the Tubular Reverse Osmosis Modules, the support racking, inter-connecting pipework and valves, the feed tank (usually stainless steel), the acid dosing tank and acid dosing pump, in line coarse cartridge filters (100 - 300 microns), and permeate manifolding. The plant should be sited in a covered area with a floor that can hold at least one ton per square meter. Fittings (pipes) to and from the plant can be standardised to the users requirements. Modules are fitted into racks which contain 72 modules, the modules being 2,5 metres in length. These racks can be stacked on top of each other depending on area constraints. The space required by a 100 m^3/day plant is approximately 20 square metres x 3 metres high while a 1,000 m^3/day plant will require approximately a 100 square metres x 4 metres high.

THE WORLD'S FIRST LARGE SEAWATER REVERSE OSMOSIS DESALINATION PLANT AT JEDDAH, KINGDOM OF SAUDI ARABIA

by

Abdullah Al-Gholaikah[1], Nabil El-Ramly[2],
Isam Jamjoom[3], and Ralph Saston[4]

ABSTRACT

Traditionally, coastal urban centers in arid regions have had to rely on distillation as the means of desalting seawater. A new reality is now available as exemplified by the current installation of a large reverse osmosis plant to desalt highly saline Red Sea water to supply municipal water needs at Jeddah, Saudi Arabia.

The Saline Water Conversion Corporation of the Kingdom of Saudi Arabia awarded a competitively bid contract to Fluid Systems Division of UOP Inc. for the design, fabrication, construction, and two-year operation and maintenance of a seawater reverse osmosis desalting plant with a production capacity of 12,000 m^3/day.

This paper presents a comprehensive review and description of the design, logistics and installation aspects of the plant together with an evaluation of delivery times and capital and operating costs of reverse osmosis vis-a-vis multiflash distillation for seawater desalination.

BACKGROUND INFORMATION

Jeddah

The City of Jeddah, situated on the coast of the Red Sea, is the largest port and most important commercial center in the western region of the Kingdom of Saudi Arabia. It serves as the port of entry for the hundreds of thousands of pilgrims who annually visit Mecca Almukaramah from all over the world.

Jeddah covers an area of about 190 million square meters and is the most densely populated city in the Kingdom. The resident population of Jeddah has constantly been increasing, especially during recent years, as a result of the ambitious industrialization and development programs undertaken by the Government. The population increased from around 40,000 in the mid-forties to about 160,000 in the mid-sixties. The 1974 Population and Housing Census shows that Jeddah had about 565,000 people at the end of 1974. Assuming an annual population growth rate of 10 percent during the past four years to take into account the large influx of foreign workers, Jeddah's population will be over 800,000 persons by the end of 1978.

Jeddah's climate is subtropical with hot, humid summer and warm winter months with occasional scanty rainfall between November and February. The average annual rainfall is a little less than four inches (10 cm) per year.

Water Supplies and History of Desalination Applications

The City of Jeddah is located in an arid region and has always been plagued with water supply problems. Because of the importance of water, it always has been necessary to develop new water resources. Consequently, many pioneering and imaginative water supply schemes were conceptualized and implemented during the city's long history. It is, therefore, not surprising that the first seawater conversion plant to provide a sizable city with its drinking water needs was installed in Jeddah.

Toward the end of the Nineteenth Century, it was decided to import a distillation apparatus that had just been developed in Europe. In 1907, this new invention was purchased from the United Kingdom and installed in Jeddah. Despite the many operating and technical problems associated with that apparatus, known in Jeddah as the

Kendase (condenser), the local inhabitants, through ingenious maintenance and repair schemes, managed to keep it in operation until 1934 when it was replaced by a larger plant made up of two distillation units.

Because of the increase in water demand, especially created by the increase in the number of pilgrims, it was necessary to operate the two units well above their rated capacity and, therefore, many operating problems were encountered. Nevertheless, this plant continued to provide the City with its drinking water until about 1960 when it was dismantled, partly because of inefficient operation but mainly because a water pipeline had been constructed to bring water from wells and springs in Wadi Fatima, about 86 km east of Jeddah. Wadi Fatima water was subsequently augmented by water from Wadi Khuleys, some 100 km north of Jeddah.

Although water transportation from Wadi Fatima and Wadi Khuleys is still providing Jeddah with fresh water in an amount ranging between 15 and 20 mgd (68800 – 76700 m^3/d), with the great increase in industrialization and the consequent increase in population, these sources were found inadequate and the need to supplement fresh water supplies was imminent. Accordingly, in 1965, after careful and detailed studies of local and technological factors, it was decided to embark on an ambitious desalination program with far-reaching ramifications. The supervision of the implementation was first carried out by Saline Water Conversion Office (SWCO) a department of the Ministry of Agriculture and Water. In recognition of the benefit and importance of this program to the Kingdom, a Royal Decree was issued in 1974 to establish an independent government agency, the Saline Water Conversion Corporation (SWCC), to be in charge of the desalination programs in the entire Kingdom. His Royal Highness, Prince Mohamed Al-Faisal, an internationally recognized desalting pioneer, was named the first Governor of that agency.

The Need – Water Supply/Demand Balance

Table 1 lists the seawater desalination and power projects, in operation or under construction in Jeddah, that have been contracted for by SWCC. The seven projects indicated in this table can be categorized into two groups.

The first group includes the four major and permanent projects, Jeddah I through Jeddah IV. These are dual-purpose plants, with combined capacity of 830 megawatts of electricity and 86 million gallons per day (322,000 m^3/day) of desalted water, that have been planned in relation to the long-range increase in water and power demands. (See Figure 1.) The construction of these permanent installations is being staged in four phases to minimize under-utilization of installed capacity during early years and thereby optimize capital allocation over time. Of course, in staging the four Jeddah phases, consideration was also given to such aspects as the availability of local construction labor, the impact of these large projects on the world desalination industry, operation and maintenance constraints, and other economical and technological factors.

The second group includes the remaining three projects in Table 1, which are relatively small and may be regarded as being of an urgent or temporary nature. These were undertaken, in relation to short term deficiencies in the supply/ demand balance, to alleviate temporary unsatisfied demands as depicted in Figure 1. The seawater reverse osmosis plant described in this paper falls under this group of projects. As a result, its procurement, design, lead-time, mode of operation and other considerations were influenced by its temporary and urgent role.

PLANT PROCUREMENT

Near the end of June, 1977, major reverse osmosis membrane suppliers were invited by the Ministry of Agriculture and Water, Kingdom of Saudi Arabia, to bid on a temporary 12,000 m^3/day seawater reverse osmosis desalination plant to augment the supply of potable water to the City of Jeddah. The tender document, transmitted via telex, required that the plant be supplied in the shortest possible time and requested that tenders be submitted by July 7, 1977. Upon receipt of tenders, discussions were held in Coronado, California, between the bidders and the Ministry's Engineer, VBB (Vattenbyggnadsbyran) of Sweden. On July 19, 1977, a letter of Intent/Order to Commence was awarded to Fluid Systems Division of UOP Inc. for a total lump sum of 105.30 million Saudi Riyals for plant construction and 16.45 million Saudi Riyals for two years of operation and maintenance.

SCOPE AND REQUIREMENTS

Scope of Supply

Equipment and Construction: The scope of supply includes the complete design, supply, erection, testing and maintenance of the plant from a seawater pump well to a 400 millimeter diameter water main, excluding the connection of the pump well to the seawater pipe for the disposal of the reject. The contract includes all pertinent civil works, air conditioning, power generation, seawater pretreatment, reverse osmosis desalination equipment, post treatment, and storage of all chemicals needed for six months of operation at design capacity.

*One of the nine units is stand-by. The plant also has three second stage units.

Figure 1. AN ILLUSTRATION OF WATER SUPPLY/DEMAND BALANCE JEDDAH, KINGDOM OF SAUDI ARABIA

Operation and Maintenance: The contract requires operation and maintenance of the whole plant for a period of two years. This includes all supplies and chemicals, except fuel.

Capacity Requirement and Guarantees

It is specified in the tender that the plant shall maintain the full capacity of 12,000 m^3/day in case of any single breakdown of mechanical equipment, such as pumps, chemical dosing, reverse osmosis units, etc. Furthermore, there should be sufficient capacity to ensure design capacity during normal maintenance. In other words, full load and capacity factors are required. Water production is contractually guaranteed, including provision for a schedule of monetary allowances to the owner in the event of stipulated failure to provide the guaranteed amounts and quality of water during the O&M period.

Mobility Requirements

Because of the temporary nature of the plant, the tender document stated that the plant must be sufficiently mobile so that it could be dismantled and moved to other sites after two years of operation. Accordingly, it was specified that the number of reverse osmosis units should be as few as possible, but not less than six, and the units should be able to operate independently of each other. Seawater pretreatment, however, was required to be regarded as a separate plant with a stand-by line. Extensive pretreatment to increase water recovery was discouraged.

Delivery Time

To minimize delivery time, it was required that all equipment should be of such configuration that it could be packaged in containers suitable for air-freight. Furthermore, preference was expressed for factory assembled units to minimize erection work on site.

Water Characteristics

Table 2 lists the specific characteristics of feed and product water.

General Design Requirements

- All parts shall be resistant to corrosion or be protected from it.
- Equipment shall be designed for an ambient temperature of 40°C, and a black bulb temperature of 60°C.

TABLE 2

WATER CHARACTERISTICS

Property	Seawater	Product Water After Conditioning
Temperature	32°C (Max)	–
pH	~ 8	~ 8.5
Lime Saturation Point	–	~ 8.5
TDS mg/ℓ	41,200	< 1,000
Chlorids, Cl, mg/ℓ	22,000	< 600
Sulfate, SO_4, mg/ℓ	2,960	20
Total Hardness, mEq/ℓ	148	1.4 – 2.8
Permanent Hardness, mEq/ℓ	145.5	–
Temporary Hardness, mEq/ℓ	2.5	1.2 – 1.6
Calcium, mEq/ℓ	26	1.0 – 1.8
Magnesium, mEq/ℓ	122	
Total Iron, Fe, mg/ℓ	0.2	
Silica, mg/ℓ	0.4	
Plugging Index, %	91 – 96	
Turbidity	0.5 – 0.5 as SiO_2	0.3

- Electrical equipment shall be 60 Hertz and the insulation shall be of Class 156(F) or higher. Electric motors shall be totally enclosed.
- Diesel engines and electric motors shall not be used continuously to more than 90 percent of the site rating.
- Mechanical ventilation and air conditioning areas designed for human beings shall be cooled to 26°C, and areas for equipment as needed.
- It shall be possible to use the brine for back-washing of sand or dual-media filters.
- The plant shall be equipped with the necessary instrumentation and automatic regulation devices to shut the plant down in the event the feed had not been adequately pretreated.
- The plant shall be founded on a sulphate-resistant concrete slab.
- Chemical sludge and reject (brine) shall be discharged into the sea near the plant.

PLANT DESIGN

Design Concept

To allow for maximum flexibility and reliability, and to permit later use of complete sections of the plant at other locations, the design concept chosen was to provide, as much as is practical, independent parallel operating trains. Commonality of components was employed to the maximum extent to further increase reliability and ease of maintenance.

Plant Description

The plant layout is shown in Figure 2, and the process flow diagram is given in Figure 3. These drawings should be referred to while reading the following description.

Seawater is supplied through a pipe type intake. Water is withdrawn from the ocean and conveyed through an underwater pipeline to a concrete inlet well. Water is then lifted from the seawater intake well to a splitter box by means of three low speed vertical pumps, two operating and one stand-by.

From the splitter box, the feed water flows to three 32-foot diameter (9.75 m), gravity flow, dual media filters. Filter media are composed of anthracite coal and sand. Each dual media filter is divided into three individual compartments to facilitate back-washing while maintaining the required full capacities.

The filtered water exits through the underdrain of the dual media filters into a concrete clearwell. Water is then transported from the clearwell by three pumps, again two operating and one stand-by, to a pipeline header in the building which houses the reverse osmosis units for distribution to individual units. The pumps lifting the seawater from the clearwell are identical to the pumps which lift the water from the seawater intake well.

The reverse osmosis plant is made up of first and second stage units. The plant includes nine first stage units, eight operating and one stand-by, and three second stage units. The nine first stage units are fed by individual pipelines from the distribution header. Each stream is treated prior to desalting.

Pretreatment consists of acid and phosphate addition, followed by filtration. Acid is injected into each stream to adjust the feed water pH to approximately 6.4. Also, at approximately the same injection point, sodium hexametaphosphate is added at the rate of 2 mg/ℓ to inhibit scale formation. After chemical treatment has been accomplished, each feed stream is filtered in cartridge type filters to promote chemical mixing and to remove suspended solids to protect the high pressure pumps. Cartridges are constructed of 25-micron mesh size.

The pressure of each of the nine feedstreams is then boosted by two multi-stage vertical turbine pumps, operating in parallel. Each of the two parallel pumps is directly driven by a 425 hp diesel engine. Each pump has a capacity of 500 gallons per minute (2726 m^3/day), at a discharge pressure of 1000 psi (6900 k Pa). Thus, the feed flow to each of the nine first stage units from the combined parallel operating pumps is 5432 m^3/day.

The first stage units will be run at 38.5 percent recovery. Thus, each of the nine first stage units will be producing 1663 m^3/day. This results in a combined output from the eight operating first stage units of 13,300 m^3/day.

The permeate from the first stage units flows to a common collection header. The permeate can either be routed directly to the post-treatment system or split for partial flow to the second stage units. The system's performance, either using or not using the second stage, is discussed later in this paper.

Each of the three second stage units is capable of producing 2315 m^3/day of product water from a feed of 2726 m^3/day (600 gpm). Thus, the second stage units will operate at 85% recovery. The concentrate from the second stage units will be recycled through the first stage units. One feed pump, operating at a pressure of 600 psi, is used for each of the second stage units. These feed pumps are identical to the parallel operated feed pumps on the first stage units. Also, they are driven by identical diesel engines as those for the first stage.

The combined product water output from the first and second stage units is collected in a permeate header which flows to a final permeate holding tank. In the final section of the pipeline header before entering the permeate tank, lime is added to the permeate to stabilize the product water and raise the pH to approximately 7.5. Also, near the same injection point as the lime, the product is sterilized by the addition of chlorine at approximately 2 mg/ℓ as Cl_2.

The stabilized water is then lifted from the permeate holding tank by three pumps, again two operating and one stand-by, and transported to the pipeline which goes to the City of Jeddah.

Seawater Supply

The seawater inlet is provided for under a separate contract between SWCC and a Saudi contracting firm,

Figure 2. PLANT LAYOUT 3.2 MGD SEAWATER RO PLANT JEDDAH, KINGDOM OF SAUDI ARABIA

Figure 3. FLOW DIAGRAM 3.2 MGD SEAWATER RO PLANT JEDDAH, KINGDOM OF SAUDI ARABIA

Mapher Corp. It is basically a concrete inlet well, connected to the Red Sea by an underwater pipeline. The open end of the inlet pipeline is to be 6 meters below meanride and extend approximately 2 meters beyond a coral reef shelf. At the end of the coral reef, the bottom of the sea slopes abruptly downward to approximately 50 to 60 meters. Appearance of the water is very clear. Water flows through the intake pipe into the concrete well in which trash and fish screens are placed to prevent intrusion of this type of matter into the reverse osmosis inlet.

Pretreatment Equipment

The chemical pretreatment equipment is composed of acid storage and injection pumps, hexametaphosphate storage and injection pumps, and cartridge filters.

Fouling of the membrane can originate from impurities in the feedwater, such as small amounts of iron and manganese, and from scaling caused by carbonate or non-carbonate hardness. The effects of iron and manganese can be greatly reduced by pH control and filtration. Another benefit of acid addition is the removal of sufficient bi-carbonate from the feed, thereby avoiding the occurrence of calcium carbonate scale on the membrane surface.

Nine acid addition systems, complete with feedback control for pH adjustment of feedwater to the reverse osmosis plant and with required interlocks for safe plant operation, are provided. Also provided are nine sodium hexametaphosphate addition systems for scale inhibition, and nine stainless steel cartridge filters.

The pH control loop will measure pH after the cartridge filters and will be used as a signal for simple on-off control of the acid injection pump. Extended time high pH will be interlocked for individual unit shut down. Care is exercised in the acid piping to assure anti-siphon conditions.

Reverse Osmosis Units

The nine first stage reverse osmosis units are each composed of 56 Fiberglass pressure tubes (Model 56FRP-6) 160 mm diameter by 6.5 m long. (See Figure 4.) These pressure tubes are piped in parallel. Each tube contains six TFC™ Model 1501PA spiral wound high pressure elements with polyamide membrane resulting in a total of 336 membrane elements for each first stage unit. One of the units is shown in Figure 4 which is 7 meters long by 3 meters wide by 3 meters high.

Each of the three second stage units is composed of 56 FRP pressure tubes identical to those of the first stage. But, these units are piped in a configuration such that water flows through a three-pass system composed of 32 tubes in the first pass, 16 in the second pass and 8 in the third pass. This means that the second stage units are piped as a 32-16-8 array.

The plant uses Fluid Systems' polyamide thin film composite membrane element, Model 1501 TFC. The element is spiral-wound 6-inch in diameter and 40-inch long. It has a design permeate flow output rating of 1600 gal/day at 400 psi net driving pressure at 25°C. This requires an applied pressure, depending on temperature and ocean water salinity (and corresponding osmotic pressure) of 800 to 860 psi for a system operating at 30% product water recovery. The salt passage, for design purposes is 1.1% (98.9% rejection) based on chloride ion transport.

The design flow rates for the first and second stage units are given in Table 3. The last entry of this table gives the total permeate from the plant when all of the first and second stage units, except the one stand-by first stage unit, are operating, under such a situation, the overall recovery from seawater intake to final permeate will be 27.8%.

TABLE 3

MAJOR FLOW RATES*

Stream	Rate of Flow	
	m^3/d	gal/min
(1) Seawater intake	43,882	8,010
(2) First stage feed (8 units)	43,086	8,800
(3) First stage permeate (8 units)	13,300	2,440
(4) Second stage feed (3 units)	8,177	1,600
(5) Second stage permeate (3 units)	6,945	1,376
(6) Total permeate (3) - (4) + (5)	12,086	2,216

*Design conditions corresponding to a situation when all the first and second stage units, except the stand-by first stage units are operating.

Modes of Operation

During the initial operation of the first stage units, it is expected that the permeate TDS will be between 850 and 900 ppm while operating at a pressure of approximately 860 to 870 psi. (See Figure 5.) With passage of time, however, it is anticipated that the TDS of the permeate from the first stage will gradually increase. As indicated in Figure 5, at some time during the first two years, the TDS of the first stage permeate may exceed the specified limit of 1000 ppm. If and when this happens, the second stage units will be employed.

Figure 6. 1982 m^3/DAY SECTION OF THE 13,200 m^3/DAY SEAWATER RO PLANT, JEDDAH, KINGDOM OF SAUDI ARABIA

The product water quality of the second stage units will be in the range of 50 to 100 ppm TDS, depending on the quality of the feed to the second stage (i.e., the quality of the permeate from the first stage). With full plant operation, it is possible to produce a blended feed from the output of both the first and second stage units of less than 1,000 ppm TDS, even if the quality of the output from the first stage units deteriorates so that the TDS goes as high as 2,000 ppm.

Thus, the second stage units are incorporated into the design to ensure that the plant will meet the water quality requirement of the contract. This assurance, however, has resulted in an available overcapacity during the early period of plant operation. As indicated in Table 3, with eight operating first stage units, the output is calculated to 13,300 m^3/day, which is 1,300 m^3/day above the capacity requirement. Since the second stage units operate at 85% recovery, it was necessary to oversize the first stage units.

There is still another benefit that stems from the first stage units being oversized to allow for full plant capacity while operating the second stage units at 85% recovery. If the output of the first stage units is increased by only 3% (raising the net pressure by 12-15 psi or 1 atm) the required output of 12,000 m^3/day can be achieved by operating seven of the first stage units rather than eight. Thus, in reality, the plant might actually have two complete stand-by first stage units. The projected first stage, second stage, and blended product water quality as affected by time are presented in Figure 5.

ERECTION AND INSTALLATION

The major contract for this project was awarded to Fluid Systems Division of UOP Inc. and as indicated earlier, it included the erection and installation of all equipment. Two other minor contracts were also awarded by SWCC. They covered the construction of the seawater intake, and transportation of equipment from San Diego to Jeddah. At the same time, arrangements proceeded for the total organization of the project and the selection of subcontractors.

Procon Incorporated, a UOP subsidiary, acted as construction manager. Fluid Systems Division, as the prime contractor, employed locally available skills wherever possible. Civil work and electrical and mechanical installation subcontracts were awarded to Saudi firms who performed their work under the supervision of the prime contractor's field engineer and staff.

As with any project of this size and relatively short delivery schedule, some problems and delays were

Figure 5. VARIATION OF PERMEATE QUALITY WITH TIME JEDDAH, KINGDOM OF SAUDI ARABIA

inevitably encountered. They included: sea wall problems, site erosion, compaction, and delayed construction of the intake. It was necessary to change the transportation mode from air to ship. All problems were resolved within a reasonable time.

The reverse osmosis rack assemblies were fabricated and tested at Fluid Systems' facility in San Diego, prior to shipment to Jeddah. SWCC personnel verified the condition of the equipment upon arrival. Figures 6 and 7 are photographs of the completed plant taken during the final stage of its construction.

COSTS AND MSF COMPARISON

Capital Costs

The breakdown of the capital costs of the plant is indicated in Table 4. The table shows local construction and installation costs amount to about 26 to 30% of total installation cost.

To compare the capital cost of seawater reverse osmosis with multistage flash, please refer to Table 1 in which the actual contract prices of the three multistage flash plants are listed (contracted for at about the same time as this reverse osmosis plant for installation in Jeddah. Assuming a credit of $500 per kilowatt of electrical capacity, the cost

Figure 6. 3.2 MGD JEDDAH SEAWATER RO PLANT, INTERNAL VIEW

Figure 7. 3.2 MGD JEDDAH SEAWATER RO PLANT, EXTERNAL VIEW

per gallon per day of installed capacities of the Jeddah multistage flash plants would be as follows:

Jeddah II	$14.2
Jeddah III	$16.4
Jeddah IV	$ 9.4

These figures are to be compared with a $9.4 cost per gallon per day capacity for the reverse osmosis plant. It should be noted also that the reverse osmosis plant is only 3.2 mgd as compared to 10 mgd (Jeddah II), 20 mgd (Jeddah III), and 50 mgd (Jeddah IV). Taking the economy of size into account, the capital cost of reverse osmosis is undoubtedly more competitive than MSF. Furthermore, as indicated in Table 4, the reverse osmosis plant capital cost includes $2 million worth of electric generating capacity of about 6.6 MW that were not credited to the reverse osmosis plant. The owner's stipulation requiring that the plant be supplied in light, self-contained sections also significantly increased the capital cost.

The delivery time periods were one third to one fifth of those normally required for MSF plants.

TABLE 4

CAPITAL COST SUMMARY

Item	Cost Saudi Riyals
Filters	4,942,833
Electrical Equipment and Diesel Generators	3,828,843
Piping, Valves and Materials	16,908,203
R O Pressure Tube Stacks and Membrane	30,086,496
Pumps, Diesels and Motors	16,205,341
Pretreatment Skids and Storage Tanks	1,066,400
Control Panels and Instruments	720,048
Miscellaneous Hardware, Structures, Bolts, Gaskets, Paint, Grout, etc.	3,564,236
	79,121,000
Civil Work	19,250,000
Electrical and Mechanical Installation	7,000,000
	105,371,000

Energy Cost

One of the most important factors in operating costs is energy. Reverse osmosis is a relatively low user of energy, compared to distillation. Assuming a performance ratio for multistage flash of 10 pounds of fresh water per 1000 Btu and a fuel to steam efficiency of 80%, one million Btu will be needed per 1,000 gallons (3,785 m^3) of product water for a multistage flash plant.

Making the extremely conservative assumptions indicated below for a reverse osmosis plant that is similar to the upper limit values of the plant described in this paper, it will only require 1/2 million Btu for the production of 1000 gpd of fresh water using reverse osmosis, or only half of the requirements for multistage flash.

first stage recovery factor	30.5%
second stage recovery factor	85%
first stage pressure	1000 psia (6890 k Pa)
second stage pressure	500 psia (3450 k Pa)
combined pump/motor efficiency	70%
fuel to energy efficiency	30%

To demonstrate that the above assumptions are realistic, it is to be noted that the guaranteed value of fuel consumption for the plant described here is actually 500,000 Btu per 1000 gallons (3.785 m^3) of product water.

CONCLUSION

Experience to date with the design, construction and installation of this first large reverse osmosis system for the desalination of seawater has been consistent with expectations. Employment of local skills in Saudi Arabia was encouraging and satisfactory. Actual cost data accrued to date supports the contention that reverse osmosis is significantly less costly than multistage flash both in terms of capital and operating costs, even when compared to large dual purpose MSF plants. It has been demonstrated that seawater reverse osmosis systems can be erected with very short lead times compared to MSF. In summation, seawater desalination using reverse osmosis is a reality with excellent prospects for further improvements.

EDITORIAL NOTE

An earlier version of this paper was presented at the Sixth International Symposium on Fresh Water from the Sea, European Federation of Chemical Engineering, Las Palmas, Gran Canaria, Spain, September 1978.

INTRODUCTION

The DOWEX* RO-4K Permeator is a water purification module which operates on the principle of reverse osmosis to remove dissolved solids from water. Construction of the Permeator is shown in Figure 1.

Feedwater is pumped under pressure into the distribution core, where it bathes the exterior of thousands of hollow fiber membranes. If the feedwater is pressurized above its natural osmotic pressure, product water having considerably lower dissolved solids will pass through the membrane walls and into the product water line. The reject, or brine, containing most of the dissolved solids in a concentrated form, is collected through the brine outlet.

This Permeator is rated at long-term productivity of 4000 gallons per day. The 4000 gallons per day represents a theoretical extrapolation from initial test data. Initial productivity will be significantly higher, but the actual long term productivity of each permeator is influenced by a variety of factors, including feedwater temperature and pressure, dissolved solids concentration, and the presence of possible foulants or scalants in the feed. These effects, and others, will be discussed later in this manual. In general, greater than 90% of the dissolved solids will be removed.

REVERSE OSMOSIS

Reverse osmosis can be described as the separation of water from dissolved solids by application of a pressure differential across a membrane which is permeable to water, but not to the dissolved solids. The applied pressure differential must be sufficient to overcome the forces tending to keep the water and dissolved species together.

The hollow fibers contained in the DOWEX RO-4K Permeator can be visualized independently to show how they function as membranes (Figure 2). Feedwater containing dissolved solids flows over the outside of the hollow fiber. An applied pressure differential of up to 400 psi forces water through the semi-permeable walls of the hollow fiber. The dissolved species (brine) remain behind. The permeated water (product water) flows out the open end of the fiber. The incoming water has been physically separated into two streams, generating no additional pollutants.

In theory, no chemicals need be added to effect this separation, in actuality, some chemicals are required for control of pH, iron fouling, scale control, or biological growth. These and several other factors cause differences in performance of various membranes which can be of economic significance in long-term operation.

* Trademark of The Dow Chemical Company

CONSTRUCTION OF THE DOWEX RO-4K PERMEATOR

The DOWEX RO-4K Permeator consists of the following components as shown in Figure 1.

1. Case — made of filament-wound fiberglass with epoxy binder. It is designed to enclose the fibers in the pressurized compartment.

2. End plates (headers) — enclose the open ends of the fiberglass case. They are held in place by segmented rings. Sealing is provided by O-rings, and end plates may be removed by first removing the segmented rings.

   One end plate contains the product water port. The second end plate contains both the feedwater port and brine port.

3. Feedwater distribution core — allows feedwater to bathe the entire hollow fiber bundle. It is a slotted, hollow PVC tube, with a screen outer wrap. The core also adds extra strength to the hollow fiber bundle.

4. Tube sheet — an epoxy compound which secures the open ends of the hollow fiber membranes. It separates the high pressure feedwater and brine from the product water. Sealing against the case is provided by an O-ring.

5. Hollow fiber bundle — a compact bundle of thousands of longitudinally aligned fibers which surrounds the feedwater distribution core. Both ends are secured by epoxy resin, and the bundle is encased in a cloth overwrap and a polyolefin screen.

The hollow fibers which make up the membrane in the DOWEX RO-4K Permeator are cellulose triacetate (CTA). (U.S. 3,532,527)

Cellulose acetate is produced with different degrees of acetylation (different ratios of acetate to hydroxyl functionality). Some membranes use a polymer with a degree of acetylation of 5:1 (one hydroxyl to five acetate groups). The CTA polymer used in the DOWEX RO-4K Permeator is essentially completely acetylated.

The performance of reverse osmosis membranes is somewhat affected by the degree of acetylation. In general, membranes with higher acetate functionality exhibit better salt rejection, and also are more resistant to biological and chemical degradation.

The membrane in the DOWEX RO-4K Permeator must be kept wet to prevent structural changes. This is common with most membranes. Also in common with most other membranes, the rate of production of product water will decrease with time due to a phenomenon called "compaction" (see Glossary). The effects of compaction are discussed on page 8.

SYSTEMS USING DOWEX RO-4K PERMEATOR

DOWEX RO-4K Permeators must be installed in properly constructed and sized systems. Feedwater quality will dictate pretreatment requirements, which are discussed below. Figure 3 is a schematic flow diagram of the reverse osmosis portion of a water treatment system.

Treated low pressure feedwater enters the feed side of a high pressure pump and is pumped through the reverse osmosis permeator. The operating pressure is developed by pumping against a back pressure regulating device on the brine side. Concentrated brine from the permeators is discharged through this back pressure regulator to a disposal system. Multistage centrifugal pumps are preferred due to minimum pressure pulsations. Positive displacement pumps require some means of controlling high pressure fluctuations.

Product water low in dissolved solids is collected from the appropriate port in each permeator. This water may be used either as it comes from the permeator or it may require further treatment, depending upon its intended use. For staged systems brine-side pressure losses may be determined from Appendix VI.

FEEDWATER

Feedwater quality is important in reverse osmosis systems because it can affect the performance and life of the permeators and the ultimate quality of the product water. Feedwater pretreatment may be required for reliable performance. A FEEDWATER ANALYSIS is required for determining the pretreatment requirements.

Figure 4 lists the minimum information required in a feedwater analysis. In addition to this, it is often desirable to determine levels of organic matter such as organic acids, alcohols, etc. since their presence can affect performance.

Certain feedwater characteristics can affect the performance of a reverse osmosis permeator through physical or chemical interactions with the membrane.

1. **Hydrogen Ion Concentration** expressed as pH — should be between pH of 4.0 to 7.5 for optimum performance. The higher the pH (and temperature), the shorter the membrane life. CTA hollow fibers will tolerate pH levels outside the recommended range, but at the expense of long-term performance. When feedwater is highly alkaline, pH should be adjusted to a maximum of 7.5. Low feedwater pH must be adjusted to a minimum of 4.0.

2. **Feedwater Temperature** should normally not exceed 30°C (86°F) or be lower than 0°C (32°F). In common with other membrane processes, reverse osmosis permeation varies greatly with temperature. Feedwater temperatures higher or lower than the rated temperature of 25°C (77°F) will give, respectively, greater or lesser product water production than rated productivity. To help estimate productivity, Figure 5 shows the percent of rated productivity obtained with different feedwater temperatures. Please consult a Dow representative if operation above 30°C is anticipated.

FIGURE 6 Percentage of Rated Productivity as a Function of NaCl Concentration at Various Recoveries, 400 psi, 25°C

FIGURE 7 Percentage of Rated Rejection as a Function of NaCl Concentration at Various Recoveries, 400 psi, 25°C

See Figure 8 for rated passage for various ions.

3 **Total Dissolved Solids**—can affect performance in three ways. First, the concentration of total dissolved solids can affect the productivity as shown in Figure 6 due to osmotic effects. Second, some effects on rejection are also observed, as shown in Figure 7. Third, the species making up the total dissolved solids affect overall rejection due to differences in the ability of the membrane to reject them. Figure 8 shows the relative percent rejection of a number of dissolved species.

4 **Suspended Solids**—can cause deterioration of performance if not removed from the feedwater. Adequate prefiltration must be provided to ensure continuous high productivity. In general, prefiltration to five microns will be adequate. In cases where significant quantities of colloidal solids or solids of less than five microns are present, product water rates will drop as the hollow fiber bundle becomes plugged. Additional means of suspended solids removal must be used, such as polyelectrolytes or filter aids.

5 **Iron**—can reduce productivity of reverse osmosis systems by causing buildup of insoluble hydrated complexes on the membranes. In all cases, the trivalent (Fe^{+3}) form must be present in order to cause such buildup. In most cases, it must be removed in the pretreatment scheme, but sometimes the addition of sodium hexametaphosphate is sufficient to complex the iron. Iron can be removed by passage of the feedwater through green sand or ion exchange resin beds, but at the expense of ion exchange resin life.

6 **Calcium Carbonate**—can precipitate in the permeator to cause scale formation. Even if the concentration of calcium carbonate in the feedwater is low enough to be soluble under those conditions, as reflected by a negative Langelier Index (see Appendix II) scale formation may occur due to the higher concentration of solids in the brine from the permeator. In some cases, the expected concentration of hardness (as $CaCO_3$) can be calculated for the brine and checked for Langelier Index to determine scaling tendency. (see Appendix II) in many cases, however, it is better to concentrate feedwater in the laboratory to simulate the brine and check for scale formation. Both temperature and pH have an effect on the tendency for scale formation; lower pH and lower temperature will limit scale formation. Acidification of the feedwater must be to a pH that results in a negative Langelier Index in the brine. Ion exchange softening or lime soda softeners followed by acidification also can effectively prevent scale formation.

7 **Calcium Sulfate** (gypsum)—as saturation levels are approached, due to either initial feedwater quality or when saturation levels are obtained at given recoveries, saturation must be controlled either through ion exchange softening or addition of up to 20 ppm sodium hexametaphosphate (see Appendix V). Precipitation of gypsum, if not controlled, will eventually cause deterioration of performance. Barium and strontium sulfates must be similarly controlled.

8 **Chlorine**—may be present in some feedwater. The CTA membrane in a DOWEX RO-4K Permeator is resistant to attack by dissolved chlorine levels sufficient to control growth of most problem organisms (up to 1 ppm). Levels up to 5 ppm can be tolerated for shorter exposure.

All reverse osmosis membranes are subject to fouling due to growth of bacteria and "slime" in untreated feedwater. Organisms may locate in any reverse osmosis module and feed on nutrients found in feedwater. For this reason, it is often desirable to chlorinate feedwaters to control such growth in the modules as well as in pipes and storage facilities.

FIGURE 8

REAGENT	REJECTION %	PASSAGE %
NO_3^-	85	15
Cl^-	95	5
SO_4^{-2}	97	3
PO_4^{-3}	99	1
HCO_3^-	90	10
Ca^{+2}	98	2
Na^+	95	5
Fe^{+2} and Fe^{+3}	98	2
Mg^{+2}	97	3
K^+	95	5
TDS	95	5
Cl_2	NIL	—
Colloidal Solids	100	—

In order to estimate the expected passage of these ions under other conditions, refer to FIGURE 7. The TDS may be substituted for NaCl concentration. Passage listed above for ions may be modified by Percent of Rated Passage from FIGURE 7.

* Note: Empirical only. Variation is expected in mixed salt solutions due to pH dependence, common ion effect, and the necessity for electric neutrality.

PERFORMANCE

The performance of DOWEX RO-4K Permeators will vary with the temperature and quality of the feedwater, and with the operating pressure. Effects of temperature and water quality were discussed in the preceding section. Figure 9 illustrates the effects on productivity and rejection of operating pressures less than 400 psi.

Figure 10 will show expected performance changes with variation of conditions.

FIGURE 9 Pressure Effects of DOWEX RO-4K Permeator

FIGURE 10 Performance at Selected Conditions of DOWEX RO-4K Permeator

FEEDWATER QUALITY	FEEDWATER FLOW	TEMPERATURE	PRESSURE	PRODUCT WATER QUALITY	PRODUCT WATER FLOW
1500 ppm TDS	3.7 gpm	25°C (77°F)	400 psi	150 ppm TDS	2.8 gpm
5000 ppm TDS	2.8 gpm	25°C (77°F)	400 psi	700 ppm TDS	2.0 gpm
1500 ppm TDS	3.2 gpm	20°C (68°F)	400 psi	150 ppm TDS	2.4 gpm
1500 ppm TDS	2.1 gpm	25°C (77°F)	300 psi	200 ppm TDS	2.0 gpm
5000 ppm TDS	2.0 gpm	30°C (86°F)	400 psi	110 ppm TDS	2.3 gpm

OPERATION

General

DOWEX RO-4K Permeators may be operated in series, parallel, or in a combination of the two. When systems are operated in series (brine from first is feed for second), product water recovery is usually lower in each stage than with single-pass parallel operation.

Series operation is used primarily to guarantee flow in excess of the minimum brine-side flow rates needed to minimize boundary layer effects. For DOWEX RO-4K Permeator an arithmetic average brine flow ½ (feed flow + final brine flow) of 3-8 gpm is recommended. See Appendix VI for data on module pressure drop vs brine-side flow rate.

FIGURE 11 Productivity Decline Due to Compaction of DOWEX RO-4K Permeator

Startup & Storage

DOWEX RO-4K Permeators must be flushed for at least 24 hours when first installed if product water is to be used for human consumption to remove contaminants from the module. Flushing should be at operating pressure, with product water flow rates of at least 1.0 gpm. If product water is not for human consumption, flushing for several hours should remove most residual formaldehyde. For all uses product water should be tested to determine that contaminants have dropped to acceptable levels so that flushing may be terminated.

When DOWEX RO-4K Permeators are to be stored or maintained on stand-by for periods of more than three days they should be drained and refilled with a 0.5 weight percent aqueous formaldehyde solution to protect against microbial growth in the module.

Compaction

All reverse osmosis membranes are subject to declines in productivity independent of feedwater or pretreatment precautions. This decline is due to compaction of the membrane structure under the stresses of pressure encountered during operation. The degree and rate of compaction vary, with feedwater temperature and transmembrane pressure being the most significant influence.

Because compaction affects the ultimate capacity of a system to generate purified water, it is very important that it be taken into consideration in sizing a system.

To assist in sizing treatment systems using DOWEX RO-4K Permeators, Figure 11 shows productivity drop due to compaction for the particular stated conditions.

INSTALLATION OF DOWEX RO-4K REVERSE OSMOSIS PERMEATORS

General

The DOWEX RO-4K Permeator will contain a 0.5 weight percent formaldehyde solution for preservative. The DOWEX RO-4K Permeator must not be allowed to freeze. It must be protected at all times from extremes of temperature. Care should be taken when removing the DOWEX RO-4K Permeator from its packing box to avoid severely scratching the fiberglass pressure case.

Dimensions and capacities are shown in Figure 12. Permeators can be mounted either horizontally or vertically, but provision must be made to secure them and prevent undue vibration.

Feedwater

The feedwater port is tapped ½" female NPT. It will accept a variety of adapters for operation at high pressures. Galvanized and black iron fittings are not acceptable due to their associated corrosion problems.

Brine

The brine port is tapped ¾" female NPT. Adapters may be used for lines capable of withstanding the pressures to be encountered. Brine can be discharged as waste or recycled through a second bank of Permeators if desired. Galvanized and black iron fittings must be avoided.

Product

A ½" NPT female port is in the product end plate. Product water will be discharged at less than 75 psig. If it is desired to feed the product water into a pressurized water system (greater than 75 psig), appropriate tanks and pumps are necessary.

Precautions

1. Do not allow pressure of the product water to exceed that in the brine by more than 75 psig. Pressure differentials greater than this may cause internal damage due to local overpressures. This situation results most often when feedwater pressure drops quickly in system failures or shutdown.
2. Do not subject permeators to temperatures less than 0°C (32°F) or more than 30°C (86°F). Protect from freezing.
3. Do not operate permeators above 450 psig. Product pressure must not exceed 75 psig.
4. Do not damage the fiberglass pressure case. Such damage may lower the margin of safety under pressure. If modules appear to be damaged on arrival, notify the nearest Dow Sales Office immediately.
5. At full rated productivity, the average brine flow rate must be maintained between 3 and 8 gpm. In normally operating systems, the percent recovery of individual permeators should not exceed 60%.

(6.) At full rated productivity, the average brine flow rate must be maintained between 16 and 42 gpm. (See Appendix VI)

FIGURE 12 DOWEX RO-4K Reverse Osmosis Permeator

PRODUCT INFORMATION

Membrane	Cellulose triacetate hollow fibers
Configuration	Shell-and-tube
Dimensions (case length)	48 in. (121.9 cm.)
(case diameter)	6¼ in. (15.9 cm.)
Connections (feed)	½ in. NPT
(product)	½ in. NPT
(brine)	⅝ in. NPT
Shipping Weight	86 lb. (39.1 Kg.)
End Plates (feed)	PVC
(product)	304 Stainless steel
End Plate Retainers	304 Stainless steel
Pressure Case	Filament-wound fiberglass/epoxy
Feed tube O-ring	Buna N-114
Tubesheet and end plate O-rings	Buna N-365

Productivity* (design)	4000 gpd (0.63m³/hr.)
Salt Rejection*	90% minimum
Operating Pressure	0 — 400 psi (0 — 27.6 Bars)
pH Range	4.0 — 7.5
Chlorine Tolerance	1.0 ppm maximum

*At test conditions of 400 psi, 75% recovery, 29°C, and 1500 ppm NaCl

MAINTENANCE

Monitoring

Adequate means of monitoring process streams is important in all unit operations. Some means of monitoring the critical feedwater characteristics is necessary to assure proper operation of the water treatment system. Following is a list of operational limitations which should be monitored. Certain feedwaters may require additional monitoring as defined by the manufacturer.

Cl_2 (free)	≤1.0 ppm in feed
oxidants	≤1.0 ppm as free Cl_2 in feed
temperature	≤30°C (86°F)
pH	≥4.0; ≤7.5
pressure	
(feed and brine)	≤450 psig
(product water)	≤75 psig
suspended solids	≤1.0 JTU (Jackson Turbidity Units) ≤4.0 SDI (Silt Density Index)
feed source	must not vary by more than 10% from the individual system design basis in parameters which would have a negative impact on module performance

Records

Operational records must be maintained which record at least the following:

1. Feedwater quality and flow
2. Necessary chemical additives, their addition rates and monitored levels
3. Product water quality and flow
4. Brine flow and quality
5. Associated temperatures and pressures
6. Cleaning schedules, if required

Testing

Used properly, within the operational limitations, permeators should provide usable product water for many years. During this time, the combined productivity and rejection of the modules should be tested regularly. If significant changes in either occur, when compared to a previous test, then individual permeators should be tested.

Conductivity of feed, brine and product from each permeator should indicate if any are possibly defective. If no single permeators are defective, then the following checks should be made:

1. The feedwater conductivity may have increased to levels higher than anticipated;
2. pump rates may have decreased;
3. feedwater pH may have drifted outside the recommended range of 4.0-7.5, causing the membrane to partially deteriorate;
4. system operating pressure may have changed;
5. solids may have accumulated in the permeators due either to insufficient pretreatment or improper operation.

Disassembly

Normally, DOWEX RO-4K Permeators should NOT be disassembled in the field. Damage to the hollow fibers can occur due to physical shock or drying out. The module must not be disassembled by persons not specifically authorized by Dow.

Storage and Handling

DOWEX RO-4K Permeators have been tested to assure safe performance under recommended conditions for installation and operation. General guidelines for safe operation are listed below:

1. **Pressure**: The pressure case components of the DOWEX RO-4K Permeator are designed for a maximum operating pressure of 480 psig, with an adequate margin of safety. The reverse osmosis system should be designed to provide pressure protection to prevent exposure to pressures in excess of 480 psig.

   Safe operation of the DOWEX RO-4K Permeator depends upon proper installation of the end plates and support rings. These plates should not be removed or altered in the field.

2. **Storage Protection**: Permeators as shipped contain a 0.5% solution of formaldehyde for protection against biological growth. The formaldehyde should be thoroughly flushed from the permeator before the product water is collected for use.

   Because of the stability of the DOWEX RO-4K Permeator, the system can be designed for continuous or intermittent addition of chlorine to the feedwater. This makes it unnecessary to periodically shut down to sterilize the system. If the DOWEX RO-4K Permeators are shut down for periods of more than three days they should be filled with a 0.5 weight percent formaldehyde solution.

   Freezing may impair the performance of DOWEX RO-4K Permeators. In shipping, handling, operations and storage, the Permeators should be protected against freezing.

3. **Chemicals**: Operation of the pretreatment system and storage protection of the modules will involve use of toxic chemicals such as chlorine, acid, and formaldehyde. Conventional safety practices should be followed in handling these materials.

As with any other product, membrane devices must be used and disposed of in accordance with established and acceptable practices.

Many potential uses for these and other membrane products fall under requirements or restrictions imposed by various Governmental agencies. The user of these membrane devices must establish that their use is permitted under all applicable governmental regulations and statutes.

The disposal of these devices must take into consideration potential effects of not only the device itself, but also of any chemical, biological, or other agent or agents which may be associated with the device as a consequence of its use. Disposal must conform with applicable legislative requirements and governmental regulations.

If any questions arise concerning operation, performance, appropriateness or disposal of these membrane devices which is not provided for in this booklet, please contact the nearest Dow Chemical U.S.A. sales office.

APPENDIX I

Glossary

Average brine flow — the arithmetic average of the feedwater and final reject flowrates ½ (feed rate + brine rate)

Brine — (concentrate; blowdown; reject) — normally, the waste stream from reverse osmosis which contains most of the dissolved solids in the feed in a concentrated form.

Cellulose triacetate — (CTA) — a modified cellulose wherein all available reactive sites have been acetylated.

Compaction — tightening of a membrane structure due to compressive stress of operating pressure.

Feedwater — the influent water to the module.

Hydrolysis — chemical reversion of cellulose acetate back to cellulose by removal of acetate groups occurring most rapidly at very high or low pH.

Osmotic Pressure — pressure required to prevent spontaneous flow of solvent (water) into a solution when separated by a semi-permeable membrane.

Polyelectrolyte — water soluble polymers containing ionizable groups as part of their structure; often useful in causing agglomeration of fine suspended solids.

Productivity — the measurement of rated output, expressed in volume 24 hour day under a given temperature, pressure and salinity.

Product water — (permeate) — the water permeating the membrane surface of the composite module, collected at a port provided on the module end-plate.

Recovery — an expression of the feed converted into product; i.e.,

$$\frac{\text{feed rate} - \text{brine rate}}{\text{feed rate}} \times 100$$

Reverse osmosis — forced flow of solvent (water) from a solution through a semi-permeable membrane by means of pressure in excess of the osmotic pressure.

Salt rejection — defines the product quality, i.e.,

$$\frac{\text{feed concentration} - \text{product concentration}}{\text{feed concentration}} \times 100 = \text{salt rejection}$$

TDS — Total Dissolved Solids, expressed as parts per million (ppm)

APPENDIX II

Langelier Index Determination

Langelier Index Determination:

Ca ppm as $CaCO_3$ _____ Temp. °F _____

"M" Alkalinity as $CaCO_3$ _____ pH _____

Total Solids _____

(ppm Ca x 2.5 = ppm Ca as $CaCO_3$)

p Ca _____ pCa: Locate ppm value for Ca as $CaCO_3$ on the ppm scale. Proceed horizontally to the left diagonal line down to the pCa scale.

p Alk _____ pAlk: Locate ppm value for "M" alk as $CaCO_3$ on the ppm scale. Proceed horizontally to the right diagonal line down to the pAlk scale.

"C" _____ Locate ppm value for total solids on the ppm scale. Proceed horizontally to the proper temperature line and up to the "C" scale.

Sum pHs _____

Actual pH _____

Difference _____ = Saturation Index. (Actual pH – Sum pHs) Positive number indicates scaling.

EXAMPLE:

Temperature = 140 °F
Ca Hardness = 200 ppm
M Alkalinity = 160 ppm
Total Solids = 400 ppm
pH = 7.80

p Ca = 2.70
p Alk = 2.80
C at 140F = 1.68
Sum = pHs = 6.78
Actual pH = 7.80
Difference = +1.04

= Saturation Index

APPENDIX III

Empirical Estimation of Scaling Tendencies of Brine from R.O. Modules

S = T.D.S. of feed
H = Calcium hardness of feed, as ppm $CaCO_3$
A = Total alkalinity at untreated pH as $CaCO_3$
K = Alk/CO_2 ratio at untreated pH from graph
C = CO_2 level in untreated water, as ppm CO_2 = A/K
R = Desired recovery ratio
$= \frac{\text{Product-water flow rate}}{\text{Feed water flow rate}}$
K_1 = Alk/CO_2 ratio at desired pH from graph
X = Change in alk. and CO_2 units due to pH adj.
$= \frac{A - CK_1}{K_1 + 1}$
C_1 = CO_2 level in feed after pH adj.
$= C + 0.9X$
A_1 = Alk. of feed water after pH adj.
$= A - X$
C_2 = CO_2 level in brine
$= \frac{0.9C_1}{1 - R}$
A_2 = Alk. of brine
$= \frac{0.9A_1}{1 - R}$
K_2 = Alk/CO_2 ratio in brine
$= A_2/C_2$
P_2 = pH of brine from graph at K_2
H_2 = Calcium hardness of brine
$= \frac{0.9H}{1 - R}$
S_2 = T.D.S. of brine
$= \frac{0.9S}{1 - R}$
P_{sb} = Scaling pH of brine from Langelier Index Appendix II

NOTE: If $P_{sb} > P_2$ then brine will not scale. If $P_{sb} < P_2$ then scaling is indicated and either pH must be lowered or recovery must be reduced.

This estimation should be used as a guide — not as absolute. If P_{sb} and P_2 are close (say, within 0.5 units) actual tests should be made of the scaling tendency, or as noted above, pH should be lowered, or lower recovery should be accepted.

APPENDIX IV

Determination of Acid Required to Reduce pH to Desired Level

A = Total alkalinity of untreated water, as ppm $CaCO_3$

K = Alkalinity: CO_2 ratio at untreated pH from graph

C = CO_2 level of untreated water, as ppm CO_2
$= A/K$

K_1 = Alkalinity: CO_2 ratio at desired adjusted pH from graph

x = H_2SO_4 required to adjust pH, as ppm H_2SO_4
$= \frac{A - (CK_1)}{0.90\,K_1 + 1.02}$

S = H_2SO_4 required to adjust pH, as lb. per 1000 gal. feedwater
$= \frac{x}{120}$

M = HCl required to adjust pH, as lb. (100% basis) per 1000 gal. feedwater
$= .745\,(S)$

APPENDIX VI

Pressure Drop vs. Average Brine Flow For DOWEX RO-4K Permeators

APPENDIX VII

Test for Determining Silt Density Index

Equipment

1. Millipore* Filter Pad Holder with a 0.45 micron filter disc
2. 500 ml. graduated cylinder
3. Stopwatch
4. Dull tweezers

Procedure

1. Unbolt the filter holder, wet it, and place a 0.45 micron filter on the back-up plate using the dull tweezers
2. Place the "O" ring properly and then replace the top half of the filter holder and bolt loosely
3. Connect apparatus to the feedwater line (minimum 30 PSIG) in a vertical, downflow position and open the needle valve a crack
4. Loosen two adjacent filter holder bolts, tilt the apparatus and bleed out all trapped air, then retighten bolts and adjust the pressure to 30 PSI while starting the stopwatch
5. Immediately run the flow into the graduated cylinder and measure the time required to collect 500 ml, maintaining a pressure of 30 PSIG during the run. Mark the time (t) and keep the watch running
6. Repeat step 5 immediately after 5, 10 and/or 15 minutes of total elapsed time. Mark the collection times (t_5, t_{10}, t_{15})
7. Close the sample valve and disconnect the apparatus after the 15-minute reading. Remove the filter disk and place it in a plastic bag for later examination.

Calculations

1. Calculate the ratios $R = t/t_5$, t/t_{10} and/or t/t_{15}
2. Estimate % P_{30} at the selected time(s) from the following equation: % $P_{30} = (1-R) \times 100$
3. Estimate the Silt Density Index, SDI, from the following equation

$$SDI = \frac{\% P_{30}}{\text{Elapsed Time (minutes)}}$$

The 15-minute index will generally be the lowest of the three and should be used for filter sizing purposes.

Telex: 420987

INFORMATION ON EDR

The most informed information on EDR, apart from the comprehensive literature including SCHUTTE (1983), JONES (1982), and GARLING (?), KATZ (1977), BROWN and McELHINNEY (1981), ELYANOW, et al. (1981) and OWRT (1979) inserted below.

MELZER and VAN DEVENTER (1983) reported testwork of two ED units of 2 m^3/d and 130 m^3/d product flow for water recovery from cooling water blowdown at an ESCOM power station in South Africa. Their paper estimates the capital and operating costs for an EDR plant to concentrate effluent from a 3,600 MW power plant into 20% of the volume, and a further reduction to 2% of the initial volume by evaporation.

These documents provide a good idea as to the capabilities and cost of EDR. In addition, a brief description of an EDR plant at the Kriel power station, South Africa, is provided in Appendix I.

Individual experts who may be available to provide additional information include the vendor contacts:

J. MELZER

Casper, WY 82601

COMMENTS

1. The largest EDR plant to date is the 24,000 m^3/d desalination plant on the Tigris River, Iraq, which comprises six aquamite 100 modules by Ionics teating brackish water. Feedwater runs 1,800 mg/l TDS which will be reduced to 30-50 mg/l prior to polishing.

2. It is clear that significant recoveries and brine concentrations can be achieved using EDR. However, the cases cited do not demonstrate EDR ability to treat minewater or mill tailings solutions with, say, 1,500 mg/l $CaSO_4$. Certainly, it has been found that gypsum concentrations well in excess of saturation (2,000 mg/l) can be tolerated in EDR concentrates without foulding if anti-scaling agents are used, even up to 400% of saturation which would be about 8,000 mg/l $CaSO_4$. However, that would allow only 80% recovery from a minewater feed containing 1,500 mg/l $CaSO_4$. Consequently, there is a questionmark as to how applicable EDR is for that type of solution.

3. At East Rand Proprietory Mines Ltd. (ERPM), at test demonstration EDR plant was installed by the South African representative of Ionics. During a visit to another installation at this site, it was noted that the pretreatment facility at the EDR pilot plant was significantly larger than the EDR unit itself.

   No data or information were provided on the pilot test results which were not yet complete at the time of the RANDOL tour. These would provide an insight into the potential applicability of EDR to AMD treatment. The following individuals will eventually be able to release information on this test program:

4. A paper by G. A. Garling (date unknown) on an evaluation of electrodialysis for process water treatment for in situ mining of uranium in Wyoming is inserted below. For the particular solution testes, EDR appears highly suitable, bearing in mind that the feed contained 363 mg/l $SO_4^{=}$, and the brine was concentrated to 1,656 mg/l SO_4, 2,384 mg/l HCO_3, and 1,884 mg/l Cl^-. In this case, uranium was concentrated from 9.15 mg/l to 21.4 mg/l--a recovery of about 80% into the brine which could prove useful for further concentration. Although highly promising as a tool for in-situ leach wellfield restoration, this case is not a satisfactory test for highly scaling $CaSO_4$ solutions. The only really good test of that known is the ERPM minewater pilot test noted above.

5. A visit to the EDR installation at Kriel power station as described in Appendix I was convincing as to the maturity of EDR technology. These units can be installed rapidly and cleanly to result in a functional plant. The Kriel plant, which consists of two aquamite 100 modules, i.e., 8,000 m^3/d capacity, was erected and operating in a period of 12 weeks. In this case, however, the EDR duty is relatively light. Regional water at about 250 mg/l TDS is demineralized to around 40 mg/l TDS to take the load off the ion exchange polishing plant.

Electrodialysis
The First Twenty-Five Years

William E. Katz
Vice President
Ionics, Incorporated

One morning in February of 1952, the front page of the NEW YORK TIMES carried a two-column headline announcing the demonstration by a small company in Boston of a radical new method of desalting sea water and brackish water. The new method used electricity to move salts and minerals through special plastic membranes. The company was Ionics and the process was called electrodialysis. That demonstration — twenty-five years ago — has had far-reaching effects on the technology and development of water desalting. Today — in a few minutes — let us mark that anniversary by noting some of the consequences of that demonstration for users and developers of saline water equipment of all types. Our interest in the past lies primarily in what it can teach us for the future — the next 5, 10, and 25 years. Accordingly, these remarks will conclude with a listing of some challenges facing the saline water industry today, in the form of projections for the future, founded in our mutual experience to date.

For the moment, let us return to some important results of that 1952 demonstration.

First, electrodialysis in 1952 demonstrated the startling new idea that a practical desalting method could be based on a physical principle other than the boiling of water and the condensing of steam.

Second, the use of synthetic polymeric membranes in electrodialysis enlisted for the first time the prodigious ingenuity, energy, and techniques of the polymer chemist in the mainstream of water desalting research. This alliance has had major benefits in the fields of electrodialysis, reverse osmosis, and ion exchange, and no doubt in the future will yield further improvements and new processes — yet unnamed.

Third, the news of the new technology had been previewed to a delegation of senators and congressmen in 1951. Within a few months Congress passed the first Saline Water bill, reasoning that if a small company could make such a breakthrough on $100,000 of private money, imagine what a few millions in government support could do!

Fourth, electrodialysis had especially low costs on brackish waters. The availability (for the first time) of a process to treat brackish waters stimulated a whole new market — and led in the next two decades to a careful cataloguing of the inland brackish water resources of a large portion of the world. Any salty well or river became a potentially useful water resource — for the first time.

In the decade following 1952, a series of important pioneer brackish water projects were realized using electrodialysis equipment.

1) The first commercial sale of a brackish water unit was made to Arabian American Oil (ARAMCO) in 1954 to supply water to an exploration crew. ARAMCO has recently purchased modern electrodialysis equipment for their Community Water Supplies in Dhahran and other key population centers.

2) The first municipal use of electrodialysis — appropriately enough — was in 1955 by the Bahrain Petroleum Company for their community of Awali on Bahrain. This unit plus expansions and upgradings has served Awali continuously for more than 20 years.

3) A number of other units went into service in the 1950's and early 1960's in several Middle Eastern countries to supply fresh water for oil production camps, military installations, beverage bottling, fresh water production, and industrial applications. Thus the new technology has been used in the development of Middle East water supplies for almost a quarter century — and the technological feedback from those early units has made a long-term major contribution to the success of electrodialysis.

4) The City of Coalinga, California, became the first municipality in the U.S. in 1958 to treat a part of their water supply by desalting (electrodialysis).

5) In 1962, the Town of Buckeye, Arizona, became the first U.S. community to treat all of its municipal water supply by desalting — again electrodialysis. Buckeye was followed later in the 60's by Port Mansfield and Dell City, Texas, and later by Siesta Key, Florida; Gillette, Wyoming; Sanibel, Florida; and the Foss Reservoir in Oklahoma.

Summarizing, by the end of the 1960's, it was already generally demonstrated and accepted through the technology of electrodialysis that any brackish water source could be turned into fresh water, and that municipalities, industries, resorts, bottlers, and military installations could reliably operate such equipment.

Worldwide installed membrane desalting capacity aggregated about 5,000,000 gallons per day on January 1, 1970. Capacity began to increase rapidly in the 1970's, aided by a major marketing and technological push from reverse osmosis, and, more recently, by a very basic improvement in electrodialysis — namely, the development of polarity-reversing electrodialysis equipment.

Today, as we meet in San Diego at least two electrodialysis and two basic reverse osmosis configurations are competing in several market areas for shares of a rapidly expanding market. This vigorous commercial and technological competition has been a prime factor in the broadening of the market and in the improvement of the processes.

Our successes — all of our successes — of the past are not the issue. The question is where do we all go from here? In the next 25 years.

Perhaps many of us could agree on the following prognostications:

1) There will be substantial penetration of membrane processes into the market for desalting sea water and diluted sea waters.

2) Some radical new type of particulate pretreatment is needed and will be developed — perhaps using membranes. Polarity reversal ED has eliminated the requirement for acid and polyphosphate pretreatment for most waters — and relaxed the demands on particulate pretreatment — but the pretreatment area is still the biggest problem in the membrane field. All membrane processes have outrun — in my opinion — most conventional pretreatment processes. It is time for the pretreatment element of the system to take a great leap forward.

3) There will be a continuation of the trend to smaller intermembrane spacings in spite of the cleaning and pretreatment problem.

4) High recovery systems (90% or more) will become standard.

5) Operation of large and small desalting plants will be made simpler through the use of microprocessors and related data processing techniques. As a related development, software or technology transfer will become an integral part of desalting equipment applications — better manuals, better training, better background information.

6) There will be continued progress on the longevity of materials.

7) There will be progress on the use of thermally driven ion exchange or membrane systems because of the relatively low cost and wide availability of thermal energy.

8) The relative cost of new sources of water will rise at least as fast as the cost of new sources of energy — and in water-scarce areas even faster than the cost of energy — thus providing the economic market demand for further growth and progress in the desalting industry.

9) There will be a continuation of the trend by consultants, owners, and operators, to choose higher capital cost designs to gain lower O&M costs and greater reliability.

10) More than anything else — the progress in our industry will go to those processes and those suppliers who can deliver plants of demonstrated reliability. We have heard clear and authoritative statements of this need by speakers from Saudi Arabia and other countries earlier in this conference. The keyword for the 70's and 80's is reliability.

Those of us who were privileged to be present at the birth of this industry 25 years ago cannot help but view with pleasure the burgeoning advances in technology and the current good health of the industry. With luck, some of us may be able to meet in 2002 — to look back on fifty years of membranes. Whatever happens, the future looks bright — we can all share in it if we continue to work hard, to have faith, and to meet the requirements of the marketplace.

Let us listen well to the users!

And let us continue!

Desalting High Salinity Brackish Water Using 10-Stage EDR

by
D.R. Brown/Ionics, Inc.
K.D. McElhinney/Ionics, Inc.

Demineralization of brackish water using the Electrodialysis Reversal (EDR) process has previously been proven to be reliable and economical for feedwaters with up to 5000 ppm total dissolved solids. This is demonstrated by the fact that of the over 1000 ED units either installed or under construction throughout the world, over 500 are reversal systems with an aggregate capacity of over 150,000 M^3/Day. Paralleling this rapid growth in EDR installations, there have been continuing research and development programs to expand the applicability of the EDR process. One such program has resulted in the development of EDR technology capable of treating high TDS feedwaters with up to 15,000 ppm TDS. This paper will review the design and operation of an EDR installation which has been operating in North Africa since January 1980, producing over 300 M^3/Day (~80,000 GPD) of potable water from a 9700 ppm TDS feedwater.

HISTORY

A unique opportunity to demonstrate this capability arose in 1978 when a Middle East oil company experienced failure of their distillation plant. The location of the plant was at a terminal site located on the coastal fringe of the Sahara Desert in North Africa. As the distillation plant was over 15 years old and the required repairs were too extensive, the company resorted to trucking in water. It was quickly realized that this was unacceptable due to varying and generally poor water quality and exorbitant costs (170 M^3/Day at about \$17/M^3). A quick and reliable solution to the problem was sought. Ionics, Incorporated and other desalting equipment manufacturers were asked to supply tenders to provide a water plant with a production capability of at least 225 cubic meters/day of potable water to World Health Organization Standards.

Two sources of water were available to supply the camp's need. The first being the Mediterranean Sea with a dissolved salt content of about 34,000 ppm and the second a series of wells containing approximately 10,000 ppm TDS. Although the salinity of the well water appeared stable, the fact that the wells were within 4 km of the Mediterranean coast brought some concern of sea water intrusion. Therefore, if equipment was used to demineralize the wells, it would have to be capable of treating feedwaters of up to 15,000 ppm TDS. Based upon their tender, Ionics, Incorporated was awarded a contract to supply and install a plant to demineralize the on site wells. A complete analysis of the raw water is shown on Table A.

PRELIMINARY DESIGN CONSIDERATIONS

Preliminary design focused on four major objectives:

a. Minimize electrical power loadings and consumption.
b. Provide sufficient desalting capability to reduce feedwaters of up to 15,000 ppm TDS to World Health Organization standards for potable water — namely 500 ppm TDS.
c. Control calcium sulfate precipitation. Feed water analyses provided by the customer showed $CaSO_4$ saturation levels of 70 to 100%. Predicted saturation levels in the brine blowdown were 130 to 180%.

TABLE A
WATER ANALYSES

	Design Feed	Actual Feed	Design Product	Actual Product	Actual Brine Blowdown
Sodium	2440	2090	115	79	3694
Calcium	575	652	7	4	1390
Magnesium	430	484	6	4	964
Chloride	3950	3687	186	111	7084
Bicarbonate	154	134	34	25	175
Sulfate	2940	2672	22	19	5000
TDS (Σ ion)	10439	9727	360	242	18307
pH	7.8	7.0	7.7	6.8	7.2
Iron (total)	5	2	0	0	0
Temp. °C	24	25	24	25	25
Langelier Index[3]	1.05	.26	—	—	.92
$CaSO_4$[4] Saturation – %	72	75	—	—	150

All constituents shown as ppm as the ion where appropriate.

d. Provide pretreatment for the removal of up to 5 ppm total iron in the feedwater.

In order for the system to be considered by the purchaser, the electrical demand of the water treatment system had to be less than the excess power available from existing generating facilities located at the camp site. In an electrodialysis system the DC power requirement (W) of the membrane array can be expressed as:

$$W \sim \frac{\text{Flow} \times \text{Change in Salinity}}{\text{Membrane Area}}$$

Thus, maximizing membrane area was an important factor towards reducing power consumption. In addition, minimizing pumping requirements would also reduce power loadings.

When considering the design of the ED system, these factors played a key role in determining which process approach to take — i.e. batch, feed and bleed, or straight-through. In a straight-through design, a sufficient number of stages are provided so that the salinity is reduced to the product level in one pass through the system. In a batch or feed and bleed operation, less stages are used and the partially desalted water is recycled a sufficient number of times to achieve product quality. Thus, the straight-through approach was preferred as the high membrane area per unit volume of production reduced DC power consumption; and the elimination of recycle pumping, besides reducing overall power consumption, substantially simplified the process system thereby improving system reliability.

Of course, there are limitations as to how many stages can be put in series before having to resort to interstage pumping. As stages are added, higher fluid pressures must be applied to the inlet of the first stage and/or lower fluid velocities must be maintained in the membrane array. Therefore, the limiting values of these parameters can limit the number of stages which can be used.

Previously, the maximum number of stages used in an EDR system was six stages. This was primarily due to the fact that on lower TDS brackish waters there was little or no demand for having more stages. Computer analyses and internal laboratory testing both indicated that ten stages would be required to provide sufficient desalting capacity for feedwaters with up to 15,000 ppm TDS. They also indicated that the significantly lower fluid velocities would still be safe enough to provide stable, reliable operation. Therefore, the ten stage straight-through approach was the most efficient system and was used as the basis for the ED system design.

As the polarity reversal feature of EDR systems has been shown to effectively control $CaSO_4$ precipitation — without chemical conditioning — at saturation levels of over 150%[1, 2] this was incorporated into the system design. The elimination of hexametaphosphates and acid dosing not only reduces operating costs, but is a distinct advantage for plants located in desolate areas where accessibility to the required chemicals is limited.

If iron bearing waters are allowed to enter an ED membrane array, the iron tends to precipitate onto the membrane surface forming a layer of slime which reduces desalting capacity and increases electrical resistance. The membranes can be effectively recovered by acid washing using the Clean-In-Place system. However, where the iron content exceeds .2-.3 ppm, the required frequency of this cleaning procedure becomes unacceptable and pretreatment for iron removal is required. When considering the pretreatment design to remove up to 5 ppm of iron, systems requiring continuous chemical dosing were eliminated due to operating costs and chemical accessibility. Therefore, the design was based on aeration followed by greensand filtration.

FIGURE A
SYSTEM FLOW DIAGRAM

FINAL DESIGN

The overall flow system is shown in Figure A and consists of the following:

a. Well water is transferred to the plant site through 4 kilometers of 300 mm PVC pipe and is discharged through a natural draft step aerator at a rate of up to 31.8 M^3/hr. (140 gpm). This ensures that adequate oxygen is present in the water for the iron oxidation reaction. The water then flows by gravity into a 320 M^3 (84,000 gallon) holding tank.

b. A low pressure feed/backwash pump then delivers the water to three 122 cm (48 inch) diameter greensand filters operating in parallel. The filters both catalyze the oxidation reaction and filter out the precipitated iron. The effluent is delivered to a 160 M^3 (42,000 gallon) filtered water holding tank.

c. The water then flows by gravity to three Aquamite X-HS units operating in parallel (refer to Figure B). Each Aquamite consists of a skid containing pumps, rectifiers, hydraulic and electrical controls, and two membrane stacks. The stacks are connected in parallel and each contains 10 hydraulic stages connected in series.

d. After passing through a surge tank, the water is transferred to the customer's elevated product water storage tank and then to distribution. An additional 320 M^3 (84,000 gallon) excess product storage tank is provided and, if necessary, can be directly connected to the distribution system through the same transfer pumps.

FIGURE B
AQUAMITE FLOW DIAGRAM

In general, three identical units connected in parallel were used in order to improve system reliability and to increase operating flexibility to more closely match plant production with camp demand. This in turn minimized electrical operating loads. In addition, this allowed the use of the standard Aquamite X unit (with proven reliability from almost 10 years experience) to serve as the basis for the EDR units. The standard skids were then modified accordingly for this application. The stacks were specially built with 2 electrical and 10 hydraulic stages. In addition, newly developed aliphatic anion membranes were used due to their improved electrical efficiency and anti-fouling characteristics.

The plant as ordered called for a complete turnkey installation by Ionics and included all necessary pretreatment equipment, water storage tanks, transfer pumps, EDR units, piping, wiring and the water treatment building to house the EDR units. The entire facility was manufactured, shipped and installed within 10 months from receipt of confirmed purchase order.

OPERATING EXPERIENCE

The entire water treatment facility was commissioned in January, 1980. During the first full year of operation, virtually no operating difficulties with either the EDR units or the pretreatment have been experienced, and the overall operation has been very stable. Table B, which summarizes the operating parameters of the EDR units, shows that they are actually producing more water of better quality with less power consumption than originally designed. Figures C, D, E and F are graphic illustrations of pertinent operating parameters over the year for one of the EDR units and are indicative of the long term system stability.

TABLE B
EDR PERFORMANCE

	Design	Actual
Feed TDS — ppm	10,439	9,727
Product TDS — ppm	360	240
Feed Temp. °C	24	25
Product Cap. — M^3/Day	268	305
(GPD)	70,900	80,600
Recovery — %	40	40
Power Consumption —		
KWH/M^3	9.25	7.66
(KWH/KGAL)	35	29

Note: The above figures are total for 3 units.

FIGURE C
CAPACITY VS. TIME

FIGURE D
PRODUCT TDS VS. TIME

FIGURE E
STAGE I ELECTRICAL RESISTANCE VS. TIME

A number of interesting observations were made regarding the first year's operation:

a. After start-up, the dissolved iron level of the well water dropped and stabilized to about 2 ppm. Aeration and retention reduced this to about 1.7 ppm. The greensand filters reduce total iron to 0. Although frequent backwashing is required, filter regeneration with potassium permanganate is done only once very 4–6 months.

b. Immediately after the polarity reversal in an EDR system, a period of flushing occurs where the previous brine compartments flush out with dilute water. During this period the product water is off specification and returned to the feed tank. As the instantaneous throughput is limited by such parameters as stack inlet pressure, this flushing period effectively reduces production capacity, since the unit is producing on spec water only 80–90% of the total operating time. As the duration of this off-spec period is fixed, an effective way to reduce the percentage of off spec time is to reverse polarity less often. One unit has been modified so that reversal occurs half as often as the other two units. This has effectively increased production capacity from approximately 97.7 M^3/Day (25,800 GPD) to 109.8 M^3/Day (29,000 GPD). Figures C, D, E and F represent the operating data from this unit and show that the operation has been very stable. Pending further review of the 18 month operating data, it is planned to modify the other two units accordingly. This will increase total plant production to approximately 330–340 M^3/Day (87,000–90,000 GPD).

c. Figure D represents product TDS over the year. In June, the hydraulic and electrical settings were slightly readjusted to increase production capacity and to increase product TDS from 250 to 300 ppm thereby reducing the corrosive properties of the product water. Since then, product TDS has remained very stable at the 300 ppm level.

d. By plotting the electrical resistance of the membrane array versus time, one can determine if there has been any appreciable loss in membrane capacity. An increase in resistance usually signals a loss of capacity. Of course, increased electrical power will also be required to achieve the same demineralization. As feedwater temperature fluctuation (which does vary from 25 to 28°C) will change the stack resistance, the data has been corrected for a constant 25°C feedwater basis. Figure E represents the electrical resistance of the first electrical stage vs. time. As can be seen, the resistance has been very stable and there has only been a slight increase (~3%) over a period of the year.

FIGURE F
POWER CONSUMPTION VS. TIME

e. Figure F represents the total electrical power consumption versus time. Again, the process stability is evident as power consumption has consistently been in the 7.4–7.7 KWH/M^3 (28–29 KWH/1000 Gal) based on a 25°C feedwater. The aliphatic anion membranes have contributed significantly toward reducing power consumption due to their superior electrical efficiency.

f. The polarity reversal function of the EDR units has effectively controlled calcium sulfate precipitation. There have been no operational difficulties caused by scale formation despite having 140–160% saturation in the brine waste.

g. In addition to the reversal process, the system is kept free of scale accumulation by periodically washing the membrane array with a mild (5%) acid solution. This is accomplished without requiring stack disassembly using the Clean-In-Place (CIP) system. In addition to the conventional CIP system which flushes the entire membrane stack, these units have been fitted with a special CIP system just for the electrode compartments (ECIP). In many applications, the first signs of scale accumulation occurs in the electrode compartments. This then determines the normal CIP frequency even if the main sections of the stack show no signs of scaling.

Therefore, by acid washing the electrode compartments separately, the normal CIP frequency can be substantially reduced. Since the ECIP uses substantially less acid than the CIP, the overall acid consumption is significantly reduced — by as much as 50%. In addition, the ECIP can be performed while the unit is in operation. Therefore, the total system downtime required to perform the CIP's is reduced. ECIP is normally performed for about ½ hour every 3 days. CIP is performed for 1 hour every 15-20 days. Total acid consumption for all three units is approximately 4.6 M^3 (1200 gallons) of 38% HCl per year.

h. These units have been fitted with a new reversal sequence in which the reversal of the inlet and outlet diversion valves and the DC polarities are phased in a specific sequence. This has substantially reduced the off spec duration after reversal thereby increasing production capacity by 8 M^3/D (2100 G/D) per unit. Subsequent testing on another ten stage unit has resulted in a further modification of this reversal sequence allowing for even greater production capacity increases. This new system is now being transferred to conventional EDR units and will result in production capacity increases of about 10% or more with essentially no impact on membrane area requirements or total capital cost.

i. As the salt ions are transferred through the membranes in an ED system, some water molecules are transferred with them. In conventional EDR systems operating on low brackish waters, this amount of water is insignificant. However, on higher TDS applications it can become significant. Membrane selection can become important since different types have varying resistance to this water transfer. The aliphatic anion membranes showed excellent capability at resisting water transfer. However, a different cation membrane with tighter matrix structure would substantially reduce total water transfer. Tests on a subsequent 10 stage unit with the same anion and tighter cation did indeed result in a reduction in total water transfer by 50%.

j. Membrane replacements during the first year's operation totaled approximately 3% of total installed membranes. Based on membrane analyses and the stack resistance data, average membrane life is expected to be at least 10 years.

CONCLUSION

We believe that the performance and stability of operation of these units has demonstrated the ability of electrodialysis reversal systems to successfully and economically treat high TDS brackish feedwater. Also, the ability of EDR systems to successfully operate on high calcium sulfate waters without the need of continuous chemical conditioning of the feedwater has once again been shown.

The fact that these systems are based on standard Aquamite units has another important implication. That is, for applications where the feedwater TDS has substantially increased since the time of unit purchase or start-up, it is relatively simple to convert the units to a larger number of stages, thereby maintaining acceptable product quality.

Finally, high TDS feedwaters can also amplify certain systems dynamics making optimizations and improvements more apparent. Thus, development of the 10 stage EDR process has actually resulted in many systems improvements for conventional EDR systems. As additional high salinity plants (which are now either planned or under construction) come on line, additional design improvements for both salinity and standard brackish water units will undoubtedly result. This extra bonus helps confirm the need for continued development and refining of water desalting technology.

The Determination of Supersaturation Limits In An EDR Unit With Aliphatic Anion Membranes

by
David Elyanow/Ionics, Inc.
Ernest Sieveka/Office of Water Research and Technology
James R. Mahoney/Ionics, Inc.

I. SUMMARY

Test work done as part of the Office of Water Research and Technology (OWRT) Contract #14-34-0001-9510 "Parametric Test of an Electrodialysis Reversal System with Aliphatic Anion Membranes", had as one of its objectives the determination of upper limits of calcium sulfate supersaturation on the performance of an EDR unit with aliphatic anion membranes. For test purposes, an Ionics EDR system was installed at the OWRT Roswell Test Facility and Operated using simulated Alamogordo water[1] (approximately 42 EPM% calcium sulfate) and progressively higher recoveries.

The determination of supersaturation limits for calcium sulfate in the operation of an EDR unit became of special interest when the Office of Water Research and Technology selected EDR as the process to be demonstrated in a proposed brackish water demonstration plant at Alamogordo, New Mexico, under Public Law 95-84, Desalting Demonstration Plant Program. Although this project has not been authorized and only feasibility studies have been completed to date, the desire to achieve high product recoveries on the high calcium sulfate waters anticipated as feedwater to the proposed Alamogordo plant, resulted in a need for field studies to support future design work. Accordingly, OWRT sponsored field tests under a contract with Ionics, Inc. to explore more fully the limits of calcium sulfate supersaturation permissible in the concentrating stream of an EDR unit, with or without chemical additives, as well as the most recently developed aliphatic anion membranes. The OWRT facility at Roswell was chosen as a location for these tests using simulated Alamogordo feedwater since adequate test facilities and laboratory service could be more readily supplied at Roswell.

The EDR stack which was tested consisted of primarily aliphatic AR 204 SXZL anion membranes together with small section containing various types of test membranes. These test sections were meant to serve as a screening function to determine the optimum membrane for resistance towards calcium sulfate scale. Tests were started with zero chemical feed, 100% calcium sulfate saturation, and a Langelier Index of 1.7 in the waste stream. Recoveries were increased for several more tests until scaling occured in the skid piping and stack at a Langelier Index of 2.45 and calcium sulfate saturation of 230%. The scale was predominantly carbonate. Acid injection into the brine stream to a Langelier Index of approximately 2.0 was tried next, resulting in severe gypsum scaling in the piping, seizing of the brine recirculation pump, and little to moderate gypsum scaling of the membranes. The calcium sulfate level at this point was roughly 245% of saturation. After cleaning the EDR unit with a 24 hour 5% hydrochloric acid soak and several rinses the unit was restarted with both acid and sodium hexametaphosphate (SHMP) fed into the brine stream. This allowed trouble-free operation at recoveries up to 93.5% and calcium sulfate saturation levels of 440%. Stack inspection showed adequate performance by all membrane types, with the AR 204 RXZL singled out as the potentially least scale prone membrane.

The economics of acid and SHMP were considered and, based on Roswell chemical consuption, the cost for operation of a 2 MGD facility at Alamogordo was estimated at $.005/K gal. product for sulfuric acid and $.0045/K gal. product for SHMP for a total of $.0095/K gal.

In conclusion, using acid and SHMP together with EDR, it may be economically and physically feasible to operate at $CaSO_4$ saturation levels of 440%, thereby allowing high recoveries on difficult to treat waters without resorting to expensive lime, lime soda, or ion exchange pretreatment.

II. DESCRIPTION OF THE ELECTRODIALYSIS REVERSAL SYSTEM AT THE ROSWELL TEST FACILITY

The Electrodialysis Reversal (EDR) system at the Roswell Test Facility consists of an Ionics AQUAMITE X EDR plant containing the following components:

1) An hydraulic/electrical skid containing feed and brine pumps, a 10 micron filter, pressure regulating valve, a DC rectifier, reversal valves, and associated control and monitoring equipment.
2) A membrane stack containing 450 cell pairs in 3 electrical and 6 hydraulic stages and using Ionics' Mark III-4 spacers, CR 61 CZL-386 cation membranes, and predominantly 204 SXZL aliphatic anion membranes. Thirty-six cell pairs of other anion membranes are inserted in test sections in the first and sixth hydraulic stages. These test sections consist of 5 cell pairs each of 204 RXZL, developmental 304 RXZL and 304 SXZL, and 3 cell pairs of 103 PZL anion membranes.
3) An instrument cabinet for the monitoring and recording of feed, product, and brine conductivities, and for monitoring the electrical energy to the rectifier in kilowatt-hours.
4) Composite samplers to catch representative samples for either short-term runs (30 min.) or long-term runs (ca. 150 hrs).
5) Feed, product, and electrode water meters to obtain production and recovery data.
6) CIP tank — which is used with the brine recirculation pump for routine chemical clean-in-place procedures.

Feed water to the EDR unit is composed of a blend of facility well water (6000 ppm) and Roswell city water (approx. 900 ppm) to produce a roughly 42% gram equivalents per million (epm) calcium sulfate 1830 ppm water analagous to Alamogordo water.[1] Blending is accomplished in the same room as the EDR unit. The North well water is filtered through 10μ cartridge filters before blending to prevent sand from entering the system. Flows of the two streams are adjusted to maintain a nearly constant conductivity of roughly 2680 μmhos/cm in the blend.

After blending, the feed water is generally dechlorinated by thiosulfate injection and enters a 4000 gallon feed tank. Level controls close a 2½ inch motor operated valve (MOV) when the feed tank is nearly full. Contacts on the MOV shut down the well pump to prevent it from pumping against the closed valve. On low level, the low level controller opens the MOV, starting flow to the tank and contacts within the MOV start the well pump, thus maintaining the proper feed blend.

The EDR unit works as follows:

The feed stream is pressurized to 80–100 psig and passes through 10 micron polishing filters and a pressure regulating valve which maintains the filtrate at a constant pressure as the filters become plugged. The feed then splits into three streams — dilute, brine makeup and electrode. The predominate portion of the feed becomes the

dilute stream and travels through the diluting cells of the stack, where this stream becomes progressively demineralized until it exits the stack as the product stream. A smaller part of the feed is used as brine makeup water which combines with the brine recycle at the suction end of the brine pump to become the concentrate stream. This stream is pressurized to 60–80 psig and travels through the concentrating cells of the ED stack becoming progressively more concentrated until finally exiting the stack, where a portion goes to waste as brine blowdown and the remainder is recycled. The rate of brine blowdown is slightly greater than the rate of brine makeup due to a small amount of water transfer between the dilute and concentrate streams. The recovery of the ED unit can, therefore, be simply adjusted by changing the brine makeup flow rate.

At zero or low brine makeup, almost all of the brine stream is recirculated resulting in the buildup of high brine concentrations and, therefore, very high recoveries.

The electrode stream is the third stream taken off of the feed and is used to flush the electrodes of gases which are formed as part of the electrochemical reactions which occur in these compartments. The electrode waste stream is generally very close in composition to the feed except for pickup of oxygen, chlorine and hydrogen gases, and pH changes. Since this stream can generally be reused or fed from an alternate source, the electrode flow is monitored separately from the dilute stream by an electrode rotameter and water meter.

Polarity reversal in electrodialysis results in the concentrate and dilute cells changing identity, thus flushing out potential scale seed crystals and foulants from the former concentrating cell. Motor operated valves are used to switch these flows at the inlets and outlets of the stack. At reversal, the product becomes progressively more saline, since the product cells are now changing to concentrate cells. At a set conductivity, a controller will signal a motor operated valve to turn, diverting this "off-spec product" back to the feed tank. As the dilute stream replaces the concentrate stream in the dilute cells (which were concentrate cells before reversal), the off-spec product improves until the conductivity controller diverts the product back to product storage.

Figure one is a system diagram of the Roswell EDR unit as used in these tests and Figure two is a photograph illustrating the layout of the major components.

III. DESCRIPTION OF TESTS

The test program outlined here was performed as part of OWRT Contract #14-34-0001-6510, "Parametric Tests of an EDR System with Aliphatic Membranes". This paper deals only with the phase of this test program which has as its objective the determination of limits on the ability of an EDR system with aliphatic anion membranes to operate at relatively high recoveries on high calcium sulfate waters without extensive pretreatment. Previously, the highest percentage of calcium sulfate supersaturation which had been achieved with an EDR unit was approximately 150 percent at Dell City, Texas. The range above 150% calcium sulfate had not been explored, and there were preliminary indications that aliphatic test membranes were more scale resistant. A test program, therefore, was suggested to systematically determine the limits of calcium sulfate supersaturation with this new membrane system and was carried out during 1980 at the Roswell Test Facility.

The test program originally called for the operation of an EDR test unit at progressively higher recoveries until irreversible scaling occurs. At that time, membranes were to be replaced as necessary and tests repeated with acid and/or SHMP addition. Initially, the program was projected to operate 75 hours at 100% and 133% calcium sulfate saturation, 150 hours at 166% $CaSO_4$ saturation, and 300 hours at each subsequent increase of 33% $CaSO_4$ saturation. The actual series of tests varied somewhat from design in that much higher levels of supersaturation were obtained with chemical addition than had originally been planned. The resultant series of tests may be grouped into three phases: tests at up to 233% $CaSO_4$ with ZERO CHEMICAL FEED, a test at 233% $CaSO_4$ with acid addition to the concentrate stream, and tests at 233% to approximately 440% $CaSO_4$ with acid and sodium hexametaphosphate addition to the concentrate stream.

The design basis of these tests called for a simulated Alamogordo feed water (1780 mg/L TDS) which was blended

FIGURE 2

from Facility North well and Roswell city waters. Some typical analyses for these two sources are included in Table 1, and Table 2 shows the original estimates for simulated Alamogordo waste composition. The design production and product TDS were 95M³/day (25,000 gpd) and 200 mg/L, respectively.

The actual operation of the EDR plant allowed for some variation in product TDS, production, and recovery from design setpoints, since each of these variables is dependent on a number of factors.

Rather than try to compensate for these factors, the tests were run, as nearly as possible at set dilute flow, brine makeup flow and stack voltages. Table 3 lists the average values of these settings for each test. As can be seen from this table, dilute flow was kept essentially constant. The brine makeup flow determined the system recovery for each test and was adjusted for the recovery calculated to produce the desired percentage calcium sulfate saturation. Voltage settings were changed only where low temperatures or higher recoveries resulted in lower percentage demineralizations than desired.

Table 4 outlines the duration and resultant % $CaSO_4$ saturation, recovery, and production for the plant settings given in Table 2.

The test duration is measured between the first and last loggings or between the weekly short-term composite sampling for two-week runs and does not include the total unit running time. Before the unit is logged, the system is run for roughly 3 hours to assure steady state operation. As the unit is logged in, the composite samplers are readied and long-term composites are taken of the feed, product, and blowdown streams. Logs of the important operating parameters are taken at least twice daily and these data are used in subsequent unit performance calculations. The long-term samples are taken for conductivity measurements before the final logging, and short-term composites are taken throughout positive and negative polarities during the final logging for full laboratory analysis.

IV. DISCUSSION OF RESULTS

FEED ANALYSIS SUMMARY

The Alamogordo parametric test feed analyses are summarized in Table 5. The mean value for the feed total dissolved solids was 1829 mg/L. On the average, the feed was higher in sodium, chloride, and calcium and lower in magnesium, sulfate and bicarbonate than the Alamogordo analysis. Significant variations were observed in feed composition and TDS, even though the blend was regularly adjusted for desired conductivity. This was primarily due to large variations in feed water quality, possibly resulting from part of the Roswell Test Facility product occasionally returning through the city water interconnections. The blend feed TDS/conductivity ratio is thus seen to vary from a high of .72 to a low of .626, thus making conductivity control of TDS rather inaccurate. As might be expected, the low TDS/conductivity ratio corresponds to a higher sodium chloride ratio than the higher TDS/conductivity values.

BRINE ANALYSIS & RECOVERY DATA

Table 6 summarizes the brine waste analyses for the Alamogordo parametric tests. The progression of 33% increases in calcium sulfate saturation could not precisely be met due to the large feedwater composition variations mentioned previously. One does, however, see a general progression in calcium sulfate saturation and Langelier Index (except for acid addition cases) from Test 1 at 101% to Test 7 at an average of 440% calcium sulfate saturation. The first week of Test 5 is an exception to this because of a combination of lower calcium and sulfate feed concentrations and incorrect brine make-up setting. The low calcium sulfate figure for the second week of Test 5 with acid addition is a result of this being a 5½ day composite sample rather than the usual 30 minute composite. At high levels of saturation, the longer term composite samples tend to precipitate out and, therefore, give lower waste concentrations. The 30 minute composite was not taken in this case, due to North well pump failure.

Some comparisons between short and long-term recoveries may be seen in Table 7. Considering that the long-term data is derived from conductivity measurements and TDS to conductivity ratios, the correlation is quite good.

The brine TDS and, thus, the calcium sulfate saturation levels are seen in Tables 6 and 7 to increase rapidly at high recoveries. The 93–94% recovery in Test 7 was the highest recovery possible with this apparatus, due to physical limits of electro-endosmotic water transfer and cross-leak. There is a possibility that a few percentage points higher recovery could be obtained with flatter components that have not been exposed to scale, due to lower cross-leakage.

Salt and scale trapped between membranes and spacers after stack disassembly tend to promote excess cross-leakage and leakage to the outside. The exterior leakage is the prime cause of poor correlation between water meter readings and water analyses in Table 8 for the last three tests. Avoidance of scaling conditions, better cleaning or flatter components could have avoided most of this effect.

One major result of the data in Table 6 is to place the parameters of Test 5, approximately 89% recovery, 240% calcium sulfate saturation, and 2.45 Langelier Index as the conditions where calcium sulfate and calcium carbonate precipitation become problematical. An additional, extremely important result is the demonstration of an average of 440% calcium sulfate saturation in Test 7, with acid and SHMP addition.

DEMINERALIZATION PERFORMANCE

A summary of the demineralizer data for the Alamogordo phase parametric tests is given in Table 8. Data is listed here on recovery, production, fractional demineralization, energy consumption, stack resistance corrected for temperature, composite current efficiency values, and total dissolved solids concentrations for feed, product, and waste. The subjects of feed water analysis and water recovery have been covered previously; the fractional demineralization, energy consumption characteristics, and net production are discussed in the following.

The product water salinity and fractional demineralization for the Alamogordo tests can be seen to average 234 mg/L TDS and 87.3% respectively. This value of product TDS is somewhat higher than the design value of 200 mg/L; however, the fractional demineralization is only slightly below the design value of 88.8%. The reasons for the fluctuation of product TDS for these tests are primarily due to feedwater TDS and temperature variations. The degree of demineralization is rather easily controlled by varying the rectifier output voltage, but since it was desired to keep voltage settings relatively constant, the product TDS was allowed to vary within limits.

The product water production during the first five tests was seen to vary between 27,200 and 22,600 gallons per day. This is slightly above the 25,000 GPD design. The small decrease in production between tests one and five is primarily due to a lengthening in the time the unit produces below specification product water after reversal. As the concentration of the waste stream increases, there is an increase in the time necessary to fully wash it out during reversal. The lower productivity during the tests with chemical feed is primarily due to exterior leakage problems mentioned previously. Starting out with fresh components, one would expect production values closer to those in Test 5 with zero chemical feed. One would expect some further decline in production at the higher recoveries of Tests 6 and 7, although this is not reflected in the data.

The energy consumption can be seen to generally increase with an increase in recovery. Energy is found more nearly proportional to brine salinity than to recovery. One might expect this, as current efficiency is largely a function of the concentration gradient across the membrane. The energy consumption versus brine TDS is graphically depicted in Figure 3. Here one sees the metered energy consumption range from 2.0 KWH/1000 gallons at 73% recovery to 4.0 at 93.8% recovery. The instantaneous energy consumption values are calculated from the actual stack voltage and amperages with an efficiency factor of 94% and temperature corrected to 70°F. The energy consumption using this value is seen to increase at a significantly lower rate, from 2.1 KWH/KGAL at 73% recovery to 3.6 at 93.8% recovery. This is primarily due to correction for the declining temperature during the last tests. Water losses due to stack leakage also have contributed approximately 5% to the power consumption in the last tests because of lower productivity. The increase in energy consumption with increasing brine salinity is found using Figures 4 and 5 to be due to a reduction in current efficiency with increasing waste total dissolved solids. Figure 4 shows that stack resistance decreases with increasing waste concentration, thus tending to reduce energy consumption. The drop in efficiency in Figure 5 tends to over-power this effect since the energy consumption is inversely proportional to the efficiency squared.

The efficiencies of Figure 5 are termed composite efficien-

FIGURE 3

FIGURE 4

FIGURE 5

cies, since they are based on composite samples, net production, and steady state amperage readings. Because these steady state readings are higher than the average amperages and since reversal effects are included, these values are significantly lower than steady state values. The main utility of these efficiencies values is in establishing comparisons and trends between the different recovery cases. Except for one spuriously high reading, the efficiencies tend to decrease nearly linearly with increasing brine TDS.

SUMMARY OF OPERATING EXPERIENCE

The Alamogordo phase tests were started on July 28, 1980 beginning with a two-day test at 100% calcium sulfate saturation to establish a baseline. Testing progressed as planned through to Test 4 at 200% calcium sulfate when a high voltage drop was detected across one cell pair of the E.D. stack. Upon disassembling the stack, this problem was found to be caused by a minor misassembly. Inspection revealed no traces of scale or any other problems and thus testing was continued again under the same conditions.

On August 22, the North well pump failed and Test 4 was suspended until a new pump was installed. Well pump failures due to clogging with sand or improper wiring delayed testing two other times during Test 5 with no chemical addition and during Test 6 with acid and SHMP addition.

Test 4 was restarted on August 28 operating at 220% calcium sulfate and Test 5 was started on September 4. During Test 5, some scaling was observed in the tubing entering the membrane stack. At the end of Test 5 the stack and hydraulic piping were inspected. Scaling was found both in the E.D. stack and in the brine recirculation loop. The scale on the membrane was easily acid soluble evolving gas in the process, and thus predominantly carbonate. Analysis of scale from the brine pump indicated a ratio of two parts carbonate to one part sulfate.

At this point it was decided to inject sulfuric acid into the brine stream to reduce the Langelier Index from 2.45 to roughly 2.0. Test 5 was repeated using acid injection.

Tuesday morning, October 21, the unit was found to have shut down around midnight October 20/21. Investigation showed that the brine pump would no longer turn, and had probably caused the shutdown by activating the low pressure switch. The stack was flushed out and the pump was opened for inspection. The pump was very heavily scaled (⅛–¾" deposit) on all parts. The impeller apparently had bound at the suction race way and at its base. The pump seal was clogged by a white paste and was replaced. No scale was observed in the clear plastic piping on the stack inlets and outlets.

A stack inspection showed zero to moderate scaling which did not easily dissolve in hydrochloric acid, and was presumed to be primarily sulfate. Analysis of scale from the brine pump at Roswell Test Facility showed a composition of 26.8% calcium, 73.1% sulfate, and less than 1% carbonate.

Testing was resumed on November 7, repeating Test 5 at roughly 250% calcium sulfate and using a roughly 10–15 ppm SHMP injection into the brine stream in addition to the acid injection. No additional problems with scaling occurred and testing progressed through Test 6 at 354% $CaSO_4$ saturation and on through Test 7, run at maximum recovery (zero brine make-up), averaging 4[illegible]% $CaSO_4$ saturation.

The results of field observation may be summarized as follows:

OCTOBER 1, 1980 — Operation without chemicals resulted in precipitation and scale formation in both membrane stack and hydraulic equipment at 233% $CaSO_4$ supersaturation. Scaling was predominantly carbonate type scale. None of the various membranes could be rated any better or any worse than any other membrane; e.g., Stage 1 showed loose scale in all cells, but none of the various types of membranes were scaled internally or damaged. In the sixth stage, there was no loose scale, but all the various types of membranes showed a trace amount of internal scale. Stage 2 showed general loose scale as in Stage 6.

OCTOBER 25, 1980 — Operation with addition of acid in the brine stream resulted, again, in precipitation and scale formation in the membrane stack and hydraulic equipment, at 233% $CaSO_4$ supersaturation. Scaling, however, was predominantly sulfate type rather than carbonate. There was some evidence that the RXZL formulation of both the 204 and 304 series of membranes showed

less scaling tendency than either the SXZL and standard PZL. It is important to note that all of the single test membrane new insertions made at the October 1 inspection were not scaled, indicating the possibility of previous carbonate seeding in the original test section when operating without acid.

DECEMBER 17, 1980 — Operation with both acid and SHMP in the brine stream resulted in trouble-free operation (and, without necessity of CIPs) up to the maximum calcium sulfate supersaturaton limits physically attainable with this type of unit. Stack inspection showed that the single membrane insertions made at the October 1st and 25th inspections were all scale-free (with the exception of the 304 RXZL which showed only a trace amount of internal scale) and, therefore, there is a good possibility that successful operation is feasible with all various types of the test membranes except, possibly, the 304 RXZL type

The 204 RXZL membranes (both original and new insertions) showed no trace of scaling whatsoever in both test sections and, therefore, would be considered top candidate for continued and long-term testing.

Stack inspection results are summarized in Table 9 for the various test sections and Table 10 for the main body of the stack, which is made up of SXZL membranes.

ECONOMIC ANALYSIS OF CHEMICAL ADDITION TO THE EDR BRINE STREAM AT ROSWELL

The chemical usage data from these tests were analyzed with regards towards operating costs for a 2MGD demonstration plant.

The enclosed Table 11 summarizes the chemical consumption during the Alamogordo Phase parametric tests at Roswell. Costs are based on the unit costs given in the Kaiser Alamogordo report, page 44, and are adjusted by a factor of 1.137 to correct for one year's inflation.

It should be noted that the chemical consumption and costs are based on usage per thousand gallons of product water in order to facilitate comparison. In actuality, both acid and SHMP are added to the concentrate stream alone. Since a relatively small amount of concentrate is wasted compared to production, very small quantities of chemical are required. Additionally, it should be noted that unlike many other processes which require a negative Langelier Index in the concentrate stream, acid was added to the concentrate stream in these tests to reduce the Langelier Index to roughly +2.0 (pH ≅7.0). this requires only minor quantities of acid when compared with treating a feed water to produce a negative Langelier Index in the concentrate stream.

The foregoing discussion explains the reason for the relatively low average chemical consumptions of .180 lbs. of 66° Be sulfuric acid per thousand gallons product and 0.149 lbs. of sodium hexametaphosphate per thousand gallons product water, and average chemical costs of $.005/K gal. product for acid and $.0045 for SHMP, The net impact on operations and maintenance for a 2 MGD demo plant would be $19/day for both acid and SHMP, or $9/day (30 lbs./day) for SHMP alone and $10/day (360 lbs./day) for acid.

V. CONCLUSIONS

The following conclusions may be drawn as a result of the data presented in the previous section:

1. The Langelier Index limit for EDR systems with zero chemical feed appears to be approximately +2.4, where carbonate scale formation occurs on both system piping and membranes.
2. The calcium sulfate saturation limit for EDR with zero chemical feed or with sulfuric acid addition appears to be between 220 and 250%. At roughly 250% calcium sulfate saturation, gypsum deposition on the brine piping becomes intolerable and some gypsum scale deposition occurs on the membranes.
3. Using acid addition to a Langelier Index of +2.0 in the brine stream and sodium hexametaphosphate addition, trouble-free operation was demonstrated to an average of 440% calcium sulfate saturation for 300 hours. Higher levels of supersaturation may be obtainable, but are as yet uncertain.
4. The effect of SHMP on calcium sulfate saturation has been established during these tests, but the requirement for sulfuric acid addition in addition to SHMP is questionable. Tests are planned using SHMP injection alone to prevent carbonate and sulfate scale.
5. The AR 204 SXZL anion membrane as well as all the test membranes performed adequately at high levels of calcium sulfate saturation. The AR 204 RXZL anion membrane was singled out as potentially that most resistant to calcium sulfate scaling. Full stack tests are planned in the future.

Many brackish waters in the United States and throughout the world contain sufficiently large concentrations of calcium sulfate such that potential water recovery is severely limited by calcium sulfate supersaturation. It is hoped that this work done as part of OWRT contract #14-34-0001-9510 has extended this limit so that reasonable recoveries will now be possible on waters previously requiring expensive lime softening or ion exchange pretreatments.

WATER RESEARCH CAPSULE REPORT

ELECTRODIALYSIS TECHNOLOGY

Technology Transfer
Office of Water Research and Technology
U.S. Department of the Interior

SIGNIFICANCE

THE RAPIDLY increasing need for fresh water for municipal, industrial, and agricultural uses in the United States has resulted in withdrawal of fresh water at a rate of approximately 360 billion gallons per day, almost three times the rate of three decades ago. The projections for future water requirements indicate that increasing supplies of high-quality water will be required to meet the world's future needs. The problem and needs can generally be summarized as follows:

- Adequate quantities of ground or surface water are not always available when or where they are required.
- Those supplies which are available are often contaminated or are of a higher than desirable salinity.
- Recycling or reuse of water is a desirable objective to augment natural supplies and to conserve both resources and energy.

Electrodialysis is one of the major desalting processes now in use in over 600 plants throughout the world providing about 42 million gallons per day (mgd) of purified water from brackish water sources for both municipal and industrial uses. Electrodialysis installations are operating in communities, industries, hospitals, hotels, and a variety of other locations providing potable water from brackish sources.

Electrodialysis is an ion transfer process using ion selective membranes and small quantities of electrical energy to remove or concentrate dissolved salts in water. ED offers several unique advantages over classical desalting technology. Salt can be removed to specified levels rather than total salt removal, as in distillation, which often requires some mineral replacement for taste enhancement or corrosion control. Also, the electrodialysis process can adapt to changing mineral content of either feed-water supply or desired product water. Energy requirements for the electrodialysis process are in direct relation to the quantity of salts removed. Therefore, as salt removal requirements increase, so do energy costs.

Several aspects of electrodialysis such as improved components and high temperature operation are under development to expand the economic usefulness of this process to higher salinity levels including sea water desalting.

THE PROCESS

ELECTRODIALYSIS is an electro-chemical separation technology with the capability to reduce or concentrate ionized minerals or salts in water solution. The type of energy used to perform the separation process is direct current electricity. The separation media are two types of plastic sheets, called membranes, which have the capability of selectively transferring either positively or negatively charged particles, called ions, in solution. Ions are electrically charged atoms or chemical groups.

Commercial units consist of at least one pair of electrodes and several hundred "cell pairs" of membranes and water flow spacers to achieve the required water production rate of the system. A single cell pair consists of four elements as shown in Figure 1:

- Cation selective membrane
- Ion depleting cell
- Anion selective membrane
- Ion concentrating cell

FIGURE 1.
BASIC ELECTRODIALYSIS SYSTEM

With multiple membranes and water passages located between a pair of electrodes it can be seen that alternating passages contain ion concentrating or ion depleting solution. The two flow paths are isolated and the ED process operates with a continuous flow of water through each cell. The reduction in concentration of ions in the depletion passage is a direct function of the amount of direct electric current applied and the flow rate of the water through the cell.

The electrodialysis membranes are designated as anion permeable (negative ion transfer), or cation permeable (positive ion transfer). Typical anions are: chloride, sulfate, nitrate, and bicarbonate. Cations include: sodium, calcium, and magnesium. The anion permeable membrane is an inert organic molecular structure having fixed positively charged groups in place in the membrane. Normally, this is a quaternary amine type of group. The structure of the cation permeable membrane is similar except that a fixed negative charge is in place such as a sulfonate group. Under the driving force of an impressed direct current electrical field, positively charged cations will move in the direction of the negative electrode (cathode) until they are repelled by an anion membrane. Negatively charged anions will move toward the positive electrode (anode) until repelled by a cation membrane. Ions in solution of positive charge will electrically transfer through the cation membrane by means of the fixed negative charge groups. In like manner, negative ions will transfer through the anion membrane by means of the fixed positive charge groups. Negative ions in solution will be repelled by the negative fixed charges of the cation membrane with the opposite case being true for the anion membrane.

An electro-chemical membrane cell can be constructed to remove and concentrate ions in water passages between membranes utilizing the selective transfer and rejection functions of the membranes along with a direct electric current as shown in detail in Figure 2. Water will exit from an electrodialysis cell, called a membrane stack, as two streams: a purified stream and a concentrate stream. In water desalting applications, the purified stream is the product while the concentrate goes to waste. The ratio of product to waste is normally controlled through concentrate recycle.

The removal of minerals from water by the electro-

FIGURE 2.
SELECTIVE MEMBRANE STRUCTURE

CHARGED MEMBRANES discriminate between ions in solution according to their electric charge. Two charged membranes are shown schematically. The negatively charged membrane (left) has fixed sulfonate groups. The sulfonate membrane allows positive ions, such as sodium (Na^+), to pass, but it blocks negative ions, such as chloride (Cl^-). The positively charged membrane (right) has the opposite selectivity. The positive charges are provided by a derivative of the quaternary ammonium ion (NH_4^+).

dialysis process is a function of the amount of electric current applied. The process becomes more efficent with increasing temperature up to the present commercial limit of about 110°–160°F. Process efficiency is enhanced by hydraulic turbulence in the water passage areas to aid in the transfer of ions. Process inefficiencies can be caused by scaling or fouling of membrane surfaces. Membrane efficiency also depends on the construction and materials used to manufacture the membrane since there are many different types of membranes for differing applications.

Addition of chemicals, such as acid, to the membrane stack may be required to avoid fouling of the membrane surfaces. Chemicals may also be added to improve stack operation and efficiency. This is accomplished by increasing the electrical conductivity of the water which reduces power requirements.

A special technique called polarity reversal has been developed to overcome membrane scaling and fouling problems without the addition of acids or other chemicals. This process reverses the electrical polarity of the electrodes three or four times per hour. At the same time, automatic valves reverse stream flow so that the depleting and concentrating flow paths are interchanged. This reversal causes ions to flow in the opposite direction breaking up scale forming concentrate layers at membrane surfaces. Colloids carrying electrical charges are also removed from the membrane and carried off in the waste stream. Most of the electrodialysis systems installed today use the polarity reversal system.

Certain materials, when present in the feedwater, should be removed by pretreatment. Iron or hydrogen sulfide above 0.3 ppm, manganese above 0.1 ppm, and free chlorine should be avoided. These elements along with turbidity in excess of 2 JTU are normally controlled by means of standard aeration, filtration or ion exchange techniques. These limitations apply to water desalting and their control are generally essential to maintain optimum operation and cost performance.

In food processing and chemical applications of the electrodialysis process, special membrane considerations may be required. The application of electrodialysis for industrial process use, other than water purification, should be evaluated on a case by case basis.

PERFORMANCE

DESALTING of brackish water at ambient temperature is the main commercial application of the electrodialysis process. Results of operation of two electrodialysis plants, one a 3 MGD standard electrodialysis plant and the other a 100,000 GPD electrodialysis polarity reversal plant, now operating in the United States are described in this section.

Standard Electrodialysis Plant

FOSS RESERVOIR in western Oklahoma had been idle for ten years because of the high mineral content of the impounded water. High concentrations of calcium and magnesium sulfates made this water too highly mineralized for practical domestic use. Bids were taken by the Foss Reservoir Public Works Authority on membrane plants for the purpose of demineralization of this water. On the basis of lowest evaluated cost, a 3 MGD standard electrodialysis plant was installed.

Tables 1 through 3 show actual performance data for this plant during the first year of operation. Total solids in the feedwater was 1,960 ppm with product water reduced to a salinity of 300 ppm total dissolved solids. Pretreatment consisting of coagulation and softening for the reduction of hardness and suspended solids is used. Sulfuric acid is used to reduce the pH of the brine and electrode rinse streams to prevent precipitation in the electrodialysis stacks.

Electrodialysis Polarity Reversal Plant

THE ADVANTAGES of polarity reversal can best be shown by an application where both standard electrodialysis and polarity reversal systems were used. Dell City, Texas is a location where this comparison has been demonstrated. Raw well water ranges from 2,500 to 3,000 ppm total dissolved solids with a high calcium sulfate content (approximately 78% of theoretical saturation). The product water is required to have less than 500 ppm total dissolved solids for general human consumption.

Dell City water was first treated with a standard electrodialysis plant starting in 1967. This 70,000 GPD unit was operated for nine years and ultimately replaced by a 100,000 GPD electrodialysis polarity reversal unit. The standard ED plant, fed with acid and sodium hexametaphosphate, produced good water but operation and maintenance costs were high. The high calcium sulfate content of the feed-water resulted in scaling which shortened membrane life.

The electrodialysis polarity reversal system uses no chemical feed or pretreatment. Operation and maintenance costs are significantly reduced and all system parameters are close to original design levels after two and one-half years of operation.

Capital Equipment		
Cost decreases with increase in installed daily capacity:		
Typical Range: $0.55 to $2.00 / gallon of installed capacity		

ECONOMICS

ATTRACTIVE operating and maintenance costs for desalting lower salinity brackish waters balance relatively higher capital costs for electrodialysis desalting systems. Electrodialysis generally provides the most economic treatment for waters in the range of 1000 to 3500 ppm total dissolved solids (TDS). Typically, two and one half kilowatt hours of electrical energy are required for each 1000 ppm of TDS removed from each 1000 gallons of product water. Pumping power adds about two and one half kilowatt hours per 1,000 gallons of product.

General operating cost data for ED systems are shown in Table 4. These costs are typical for medium-sized plants treating several hundred thousand gallons per day. The principal value of this table is to show the approximate proportion of costs for such factors as electric power, labor, membranes, and so forth.

Capital equipment costs vary with plant size and range from about $0.55 to $2.00 per gallon per day of installed capacity. Figure 3 shows estimated installed costs for large plant installations in the United States.

APPLICATIONS

ELECTRODIALYSIS has several unique features which make it suitable for a wide variety of process applications. The most developed application is for the desalination of brackish water. It has many other excellent and effective uses in various facets of the food and chemical process industries.

Brackish Water Desalting

AT THE PRESENT time, ED is one of the most effective processes for desalting water with mineral content in the range from 1,000 to 3,500 ppm total dissolved solids. Special considerations relative to raw water pretreatment, maintenance, water chemistry, and waste concentration can extend this range.

In 1970, ED desalting plants were producing approximately five million gallons per day of purified product water. By 1977, this figure had grown to 42 million gallons per day. Advances in the technology of the ED process and expanding markets have created this dramatic rise in process application. Many of the most recently installed plants have been supplied as packaged demineralization systems. These units are constructed and tested at the factory for ready installation at the field site. Equipment of this type ranging in production capacity from 15,000 to approximately 1,000,000 gallons per day can be supplied. Plants of larger sizes are custom designed to fit the specific conditions of application. Information about many of the ED brackish water desalting plants is given in the annual Desalting Plant Inventory Report published by the U.S. Department of Interior, Office of Water Research and Technology.

Large ED plants ranging from three to five million gallons per day have been installed in many parts of the world. The raw feed water for these plants ranges between 1,200 to 2,200 ppm of total dissolved solids. The product water is generally purified to less than 500 ppm total dissolved solids which is the current drinking water standard. Typical examples are the three million gallon per day electrodialysis plant at Kashima, Japan and the four million gallon per day plant on the island of Corfu, Greece.

Industrial Applications

IN ADDITION TO water desalination, electrodialysis and related electromembrane processes have been used for a wide variety of industrial and chemical process applications. These range in scope from the purification of by-product food materials through preconcentration of salt prior to crystallization, to recovery of chemicals from by-product or waste solutions.

In Japan, ED is used as a preconcentration process for the recovery and purification of table salt from sea water. The process has two distinctive advantages; first, the energy requirements for ED concentration of sodium chloride from 3% to approximately 20% is less than the energy requirement for conventional evaporation; and secondly, ED selectively concentrates sodium chloride while leaving other salts for discharge in the waste stream.

Whey is produced as a by-product in the manufacture of cheese. Whey is a potentially valuable food

product because it contains large quantities of protein and milk sugar. The contaminant limiting its wide-spread use for human consumption is moderate amounts of dissolved salts. These salts can be effectively and economically removed by ED or the transport depletion process. Modified ED systems can also be used to remove or adjust acid concentration in certain types of whey rendering it more viable for wide-spread food product use. Partially demineralized whey products are widely used in infant foods, ice cream and frozen deserts, baked products, and, many other products where milk protein and sugar are desirable ingredients.

The metal finishing industries offer excellent prospects for the use of ED systems for both pollution control and recovery of otherwise lost chemicals. In most electroplating operations, the parts which have been plated with the desired metal are rinsed with high purity water as a final step. The nature of this operation is that trace quantities of the metal bearing chemicals are lost in the dilute rinse water. ED can both remove these metals which might be toxic if released to the environment as well as recover and reconcentrate them for nearly direct reuse in the electroplating bath. Although the application of electromembrane technology in this field is still in demonstration stages the prospect for broad-scale application and use is excellent.

One of the important facets of air pollution control is the removal of sulphur bearing gases from the environment. Sulphur dioxide recovery from stack gases by means of caustic soda scrubbing is commonly used. The sodium salts which are generated by this procedure can be processed in electromembrane cells to split the by-product salts that are generated reforming caustic soda for reuse and generating sulphuric acid as a by-product.

The production of high purity water for use in boilers as well as other chemical and manufacturing process applications can be enhanced with membrane technology. Electrodialysis is being applied as a pre-demineralizer for removal of the bulk of naturally occurring water minerals prior to polishing by ion exchange. ED has economic advantages over ion exchange which make it an ideal candidate for this

type of service. The cost of electrical energy for removing minerals by electrodialysis is substantially less than the cost of chemicals for the regeneration of ion exchange resins. Since ED does not require regenerant chemicals, a substantially lower quantity of waste chemicals must be discharged into the environment. Membrane systems for the removal of as much as 90% of the minerals in water prior to ion exchange demineralization are now in successful use.

Although electromembrane technology has been in commercial use for approximately 25 years, it is still in some respects at an early stage of technical development and demonstration. Future improvements in ED are expected to result in substantial reductions of electric power requirements and broader application to the chemical process industries. Development of membranes and stack components compatible with higher operating temperatures (greater than 160°F) will definitely enhance the application of ED. New membrane types with greater ion selectivity and better electrochemical properties will also expand the use of the process. As more application experience is gained, better system reliability and greater versatility with respect to process application is being developed. Because of its ability as a continuous and efficient process for the separation and removal of ionized components from solution, ED and its related electromembrane processes can be expected to solve many problems in water supply, pollution control, and chemical process fields.

ELECTRODIALYSIS DESALINATION SYSTEM For Boiler Feed Water

12,000m³/day

ASAHI GLASS

The Kashima South Joint Power Plant provides power, steam and purified water to the huge Kashima industrial complex. Abundant water is available from nearby Lake Kasumigaura. However, the lake is often contaminated by water from the adjacent Pacific Ocean. Desalination equipment was needed to remedy this situation.

In 1975, an Asahi Glass Company electrodialysis desalination plant was installed. With a throughput of 2,000 m^3/Day, it was the largest plant of this type in Japan.

In 1978, Asahi delivered another desalination plant to the same complex, this one with a throughput of 12,000 m^3/Day. It is used to pre-treat boiler water.

ASAHI'S DESALINATION PROCESS

Figure 1 shows the principle of the electrodialysis desalination process using ion exchange membranes. Selectivity is achieved because the cation exchange membrane (CM) passes only cation (Na^+) and the anion exchange membrane (AM) passes only anion (Cl^-). Combined with the electrodialysis technique, ions are thus removed from salt-contaminated water. The process involves alignment of ion exchange membranes in individual stacks.

The desalination system was designed for optimum operational efficiency depending on the salt concentration in the raw water, product water, rate of water processing, and so on.

Table 1 shows three types of desalination systems. With the one-pass continuous type system, the rate of water processing depends on the rate of water circulation through the electrodialysis stacks. The number of stacks (in series) used depends on the water's salt concentration.

In the feed and bleed system, the rate of water processing is lower than the rate of water circulation. There is a feedback line to return some of the dialysed water to the raw water feed line.

The third system is operated in a batch mode, which is only practical for a small-scale operation. The Kashima South Joint Power Plant requires desalination from 800 to 160 ppm in a chloride ion concentration, at a rate of 12,000 m^3/Day. Therefore, the feed and bleed type of system is utilized.

Figure 1: Principle of the multi-cell electrodialysis process

Table 1: Versions of the electrodialysis desalination system

Item / Version	Batch system	Feed and bleed system	One-pass continuous system
Flow chart	Circulation; Filter water; Desalinated water	Desalinated water; Raw feed water	Raw water to sequentially passed across the electrodialysers in cascade connection. (Ratio of feed water = Ratio of circulation water through tank.)
	The whole volume of solution in tank is replaced after completion of the desalination.	Desalinated water is removed from the system at the same concept rate as raw water is fed to the system. (Rate of feed water < Rate of circulation water.)	
Production capacity	Suitable for small scale plant	Suitable for medium to large scale plant	Suitable for large scale plant
Degree of desalination	High desalination rate	Lower efficiency with large desalination rate	High efficiency through larger number of stacks required in series with larger desalination rate
Tank capacity	Large	Small	Small
Pump capacity	Large	Small	Small (adjusted to the actual size of the system)
Connection to other processes	Intermittent	Continuous	Continuous
Operational condition	Substantial change from large to small current in stack	Constant	Constant

OUTLINE OF THE PROCESS

Figure 2 is a flowsheet of the electrodialysis desalination process. The primary filtrate obtained by passing raw water through an existing pretreatment unit, is treated through a fully-automatic backwash-type and filter unit, and then, it passes through a cartridge-type safety filter unit to remove suspended contaminants.

The secondary filtrate thus produced is fed to the first-stage electrodialysis stacks via the first-stage desalinated water circulation tank. After partial desalination, it is fed to the second-stage electrodialysis stacks. After this, it passes through the third-stage electrodialysis stacks for continuous desalination.

When the processed water reaches the desired desalination in the desalinated water storage tank, it is fed to the water demineralization equipment. The feed rate to the equipment is automatically controlled, depending on consumption of the demineralized water.

This system is designed in three electrodialysis stages, each comprising six parallel electrodialysis stacks for continuous desalination to an arbitrary conductivity level. The system may be partially operated – a single stage, for example.

The secondary filtrate is warmed to above 25°C for more efficient desalination and is partially fed to the stacks as the concentrate for circulation. In this process, pH adjustments can be made, if necessary, by adding a small volume of hydrochloric acid. The secondary filtrate is also partially fed to the electrode rinse circulation tank. After pH adjustments and addition of a small quantity of reducing agent, it is circulated through the electrode compartments. A small drain from the electrode compartments is neutralized, if necessary, and then put into disposal.

Figure 2: Flowsheet of an electrodialysis desalination process plant installed at the Kashima South Joint Power Plant

ION EXCHANGE MEMBRANES AND ELECTRODIALYZER STACKS

1. Ion exchange membrane "Selemion"

The electrodialysis plant mentioned above uses the ion exchange membranes "Selemion CMV" and "Selemion AMV". The following table specifies the properties of these membranes.

Membrane type	Strongly acidic cation permeable membrane (Na^+-type)	Strongly basic anion permeable membrane (Cl^--type)
Thickness (mm)	0.11 ~ 0.15	0.11 ~ 0.15
Bursting strength (kg/cm²)	3 ~ 5	3 ~ 5
Specific resistance (Ω-cm)	180~240	170 ~ 230
Resistance per Unit Area (Ω-cm²)	2.0 ~ 3.5	2.0 ~ 3.5
Transport No. T-Na / T-Cl	0.91 <	0.93 <

2. Electrodialyzer stacks

The electrodialyzer stacks are the up-to-date "DW Series" specifically designed for water production.

	DW-III	DW-IV
Size of fitted membrane	86 x 112 cm	112 x 112 cm
Effective membrane area	0.423 m²	0.918 m²
Standard number of fitted membrane pairs	200 pairs	300 pairs
Electrode material	Ti-Pt plate	Ti-Pt plate

FEATURES OF THE ELECTRODIALYSIS PROCESS

This process is the most suitable desalination of water of lower salt concentration, such as the industrial water available at the Kashima Industrial Complex. The reasons for this are:

1. The recovery rate of water is so high that the loss of raw water is usually less than 10%.
2. The salt concentration in the desalinated water may be arbitrarily adjusted while being able to cope with rises of the salt concentration in raw water.
3. Comparatively simple pre-treatment.
4. Installation and running costs are cheap for desalination of raw water with a salt concentration ranging from hundreds to thousands ppm.
5. Available at high temperatures.
6. The water demineralization system can be loaded less often, resulting in lower resin reconditioning costs.
7. Asahi's inexpensive ion exchange membranes have a high reputation worldwide for quality and are readily available in any quantity.

Because of these features, the electrodialysis process will find wider applications in the future: preliminary desalination of feed water before it passes to the demineralization equipment for boiler water production, desalination of flush or waste cooling water, production of drinking water from underground or sea water by desalination.

SPECIFICATIONS OF ELECTRODIALYSIS DESALINATION SYSTEM

Basic requirements for the design

1. Quality of the raw feed water:

The primary filtrate water from the existing electrolytically formed aluminum hydroxide injection coagulation filter unit may be fed to this system.

- Chloride ion concentration: 800 ppm
- Turbidity: Less than 1 ppm
- COD: Less than 5 ppm
- pH: Approx. 7
- Temperature: 15 to 30°C

2. Quality and output of the desalinated water:

- Chloride ion concentration: Less than 100 ppm
- Output of the desalinated water: 12,000 m³/Day

3. Type of desalination system:

Feed and bleed system with 3 stages of electrodialysis, each comprising 8 stacks in parallel.

4. Hardware specifications:

- Filter assembly - 1 full automatic backwash-type sand filter unit
  - 1 safety filter unit
- Warming device - 1 unit
- Desalination unit - 18 electrodialyzer stacks of Model DW-IV (400) with 7,344 pairs of ion exchange membranes CMV/AMV and a set of accessories, such as pumps and tanks.
- Mode of operation - full automatic
- Electric facilities - 3 thyristor rectifier units
  - 1 control center
- Drain-neutralization facilities - 1 set

RUNNING COST OF THE DESALINATION PROCESS

Figure 3 gives a few examples of the curve that may be used to calculate the running cost of the desalination process, depending on different chloride ion concentrations in the raw feed water. As indicated in this figure, higher chloride ion concentrations in the raw feed water justify combined use of the electrodialysis desalination system since running cost is lower than only using the water demineralization equipment.

ELECTRODIALYSIS USED FOR DESALINATION OF WASTE WATER IN AN ESCOM POWER STATION

J. MELZER* and D. VAN DEVENTER**, Escom

Paper to be presented at Symposium on Desalination : New Developments and Industrial Application CSIR Conference Centre, Pretoria 27 October 1983

The concentration of cooling water blow-down, with the aim to reduce its volume to achieve "zero liquid discharge" from the power station, has been tested in an electrodialysis pilot plant and the results are reported. Experimental data such as water recovery, desalting ratio, electrical consumption, calcium sulphate saturation, feed water pretreatment, utilization of chemicals, and other operational and maintenance aspects are discussed. The economical evaluation of a full-size electrodyalisis plant for a 3 600 MW power station is presented.

1. INTRODUCTION

Escom is implementing the concept of "zero liquid discharge" in order to avoid the outflow of pollutants from its power stations. In a coal fired power station which is operating on "wet-evaporative cooling" with a high production of cooling water blow-down, and "wet ashing" with a high absorbance capacity of water within the ash, the balance between the effluents produced and consumed is easily achievable. This is not so in a power station operating on "wet-evaporative cooling" and "dry ashing", which requires only about half the quantity of water for ash conditioning, compaction, and dust suppression. This would be the case in two of the new power stations - Tutuka and Lethabo, where the excess of effluents will have to be treated in a concentration plant in order to reduce their volume to a magnitude to suit the absorbance capacity of the ash.

Table 1 contains a simplified effluent balance for a power station with a generating capacity of 3 600 MW, operating on evaporative cooling. In the case of wet ashing, the effluent production is balanced with its consumption, whereas in the case of dry ash disposal, there is an excess of about 5 900 m^3/d of effluents.

Different technologies for the concentration of the effluents have been considered, including evaporation, reverse osmosis and electrodialysis. This paper will deal with electrodialysis only.

From Table 1 it appears that the excess of effluents of 6 910 m^3/d can be related completely to the cooling water blow down. Fortunately enough, the feed to the ED plant can be supplied from the cooling water side-stream treatment plant. This is a conventional plant within Escom power stations and is treating a partial flow of the circulating cooling water in a lime process for partial dealkalization and softening of the water which is afterwards recarbonized by using CO_2 containing stack gases.

A simplified flow diagram containing the integration of the effluent concentration plant with the cooling water system and the side-stream treatment is given in Figure 1.

2. ELECTRODIALYSIS (ED) PILOT PLANTS AT GROOTVLEI POWER STATION

Two pilot plants have been operated at the Grootvlei Power Station in order to test the treatability of cooling tower blow-down in the ED process, the operational parameters and plant performance, the pretreatment requirements and the costing aspects. The ED pilot plants were one of U.S. Ionics and the other one of the Japanese Asahi Glass companies. The last one has been commissioned only in August 1983 and conclusive results will be achieved later this year.

The Ionics ED plant consists of two units which will be named here I-2 and I-130, with 2 m^3/d and 130 m^3/d respectively of product water flow-rate under specified operating con''tions. This project of

treatment of the cooling water blow-down with the two Ionics ED pilot units has been carried out jointly with the Water Research Commission. Unit I-2 has been commissioned in July 1982 and has been in operation until 25 May 1983, for a total of 4 785 hours. It has been operated first as an independent unit in order to establish operational parameters for the full size concentration plant. After that it operated as a second stage ED unit being fed with the brine (reject) from the first stage ED, this being the I-130, in order to establish extreme values for water recovery, $CaSO_4$ saturation levels etc. The ED unit I-130 was commissioned in February 1983 and test work is still going on. Until 6 September 1983 it has been operating for a total of 4 356 hours.

When operating independently, both units, I-2 and I-130 showed similar performances and characteristics and therefore we will refer further on to I-130 as a first stage operation and to I-2 as a second stage operation.

The Ionics ED have normally vertical membrane stacks, with continuous, non recirculating, tortuous path flow, with electrical current reversal, and are named shortly EDR. Both units, I-2 and I-130 have 4 hydraulic and 2 electrical stages each.

3. PRETREATMENT

The initial pretreatment procedure was as follow:

3.1 Chlorination to a residual of 2 mg/l chlorine before the carbon filter.

3.2 In line coagulation with a dosage of 2 mg/l slightly anionic polyelectrolyte, Dow Separan NP-10.

3.3 Multimedia filtration (CPT) (sand, anthracite, garnet) for turbidity removal.

3.4 Activated carbon filtration (ACF) for dechlorination and partial organic removal.

3.5 Precision cartridge filtration.

During the initial period of operating the Unit I-2, the requirements for the pretreatment have been established and optimized. It was found that due to the side-stream treatment, satisfactory removal of suspended matter is achieved by passing the water through the multi-media filter, without the addition of polyelectrolyte. The activated carbon filter was found superfluous and has been bypassed. Initially the hypochlorite has been fed upstream of the MMF, continously, and the traces of residual free chlorine removed by the ACF, but organic fouling occurred on the membranes, and thereafter shock chlorination in the filtered water storage tank has been introduced. This was a partial improvement only and further changes in the chlorination practice might be required.

Hydrochloric acid addition has been found unnecessary when operating under normal conditions i.e. after the feed water to the EDR unit has been properly dealkalized, softened and recarbonated in the side-stream treatment plant.

Sodium-hexa-meta-phosphate (SHMP) addition has been found necessary only to the brine stream of the I-2 unit when operating as the second stage process where $CaSO_4$ saturation levels higher than 150 % are reached.

4. TEST RESULTS FOR NORMAL OPERATING CONDITIONS

Under normal operating conditions, the feed to the Unit I-130 was the product from the cooling water side-stream treatment plant and multimedia filtration and chlorination. The reject from this unit was fed to the second stage unit I-2 where SHMP was added into the brine stream. I-130 was operating on 80 % water recovery and I-2 on 50 %. The flow scheme and the water analyses of the different streams are given in Figure 2 and Table 2.

Operational data for the period 8 May 1983 to 14 May 1983 with daily average values are given in Table 3 and Figure 3. The operating

conditions might be called normal, because there was no reduction in the performance of the plant during this period, although there were significant variations in the salt content in the feed water to I-130 from 1 100 to 1 752 mg/l TDS and to I-2 from 4 171 to 7 588 mg/l TDS, as well as in the $CaSO_4$ concentration levels in both units.

5. TEST RESULTS AT HIGH $CaSO_4$ CONCENTRATIONS

Figure 4 summarises the period between 19 March 1983 to 6 April 1983 during which very high $CaSO_4$ saturation levels have been experienced in the brine stream of Unit I-130 of 200 % and up to 350 % for about seven consecutive days without any addition of antiscaleant (SHMP). No performance reduction of the plant during or after this period has been detected.

6. TEST RESULTS DURING FAULTY PRETREATMENT

During the whole month of July the pilot plant has operated on low grade feed water containing high bicarbonate alkalinity and high turbidity, because of the cooling water side-stream treatment and the recarbonation plant have been out of commission for different length of time. Consequently the feed water was untreated cooling water. A spot sample of 14 July 1983 showed an alkalinity content of 120 mg/l as $CaCO_3$ instead of about 50 mg/l. This happened more than once before, but not for so long a period. Also the suspended matter contained in the cooling water could not be filtered out sufficiently in the MMF as this has been operating without in-line flocculation, and consequently a turbidity of nearly 1.2 FTU has been monitored after the 10 micron filter, instead of one third of it. In addition to this, the MMF has been completely bypassed during 23 July 1983 to 24 July 1983 after being backwashed, due to an operators mistake.

This accumulation of mishappenings was a very fortunate occasion to test the pilot plant under prolonged adverse operating conditions. This period is summarized in Figure 5. It can be seen that the plant performance declined, the product water flow rate dropped from above

130 to less than 110 m^3/d during constant pump discharge pressure and constant water recovery ratio. Also at constant voltage applied to the stack, a decrease in the current density was monitored, in both electrical stages. Probing with voltmeter showed an increase in the voltage drop across groups of cellpairs. The above symptoms indicated a continous build-up of solids within the stack.

Three CIP-cleaning in place, have been performed during 20 to 22 July 1983, one clean each day, and after each cleaning operation which lasts less than one hour, operation was resumed. Only after the third cleaning, the performance seemed to be restored when the flow rate and the amperage started rising, but soon after, they dropped again. The conclusion was that the solids accumulated in the stack can not be removed by CIP and consequently the stack has been opened and dismantled for inspection on 4 August 1983.

Heavy scaling was evident in the first hydraulic stage. In addition, most of the membranes and spacers of the stack were covered with slime. All the components of the stack were manually cleaned, and a number of damaged membranes as well as some spacers which have been damaged during the opening of the stack, have been replaced. After the stack has been reassembled, a thourough CIP has been carried out - first with 5 % HCl and afterwards with a mixture of 5 % NaCl plus 5 % NaOH at pH of 10,2. The plant was recommissioned and after the 9 August 1983 it was found that its performance has been restored back to normal.

7. ECONOMICAL EVALUATIONS

Assuming an effluent balance as given in Table 1 and taking into consideration the test results on the EDR pilot plant, the effluent concentration plant for a 3 600 MW power station can be conceptualized as containing two stages - electrodialysis to reduce the volume to 20 %, and evaporation, to further reduce the volume to 2 % of the initial value. A schematic water and salt balance for the two concentration stages is given in Figure 6.

The economical evaluation is given in Table 4. The capital investment is R5 200 000, total operating cost is R441 000/ year. The PV-present value calculations for 30 years operation show a nett gain of R180 000. The overall cost of the recovered water is 35 cents/m^3, incidentally the same as the raw water of the same quality.

8. CONCLUSIONS

Although experimental work is still in progress, the following can be concluded in regard to the concentration of the cooling water blow-down at the Grootvlei Power Station by the EDR process.

8.1 The pretreatment of the feed water to the EDR plant as accomplished in the cooling water side-stream treatment i.e. dealkalization/softening plus recarbonation, followed by multi-media filtration and adequate chlorination, are sufficient for a continuous normal operation. No active carbon filtration is required

8.2 No addition of acid or antiscaleant to the feed or to the brine stream is required when operating at a $CaSO_4$ saturation level below 150 % in the brine stream. This corresponded to 80 % water recovery.

8.3 Feed water salt concentration might vary within broad limits in terms of TDS, as experienced - from 1 100 to 1 800 mg/l or more provided the $CaSO_4$ concentration in the brine does not exceed that saturation level.

8.4 At constant water recovery, the increase in feed salinity resulted in higher current density, hence higher current consumption per unit product volume, and in lower desalination ratio.

8.5 At higher water recovery rates and at higher saturation levels of $CaSO_4$ concentrations, antiscaleants have to be added to the brine stream. The antiscaleants tested, SHMP, Calgon Cyanomer P70 gave inconclusive results, and more work will have to be done on this.

8.6 The plant can operate satisfactory with improper pretreatment provided the upset conditions last hours and not days and consequently a CIP might be necessary to re-establish the plant performance. In case where the side-stream treatment is operating but not the recarbonation, acid addition to the brine stream might be required.

8.7 Normally CIP is required once a month on a prescheduled, preventive basis.

8.8 In case of prolonged operation with a nontreated feed water, scaling of the membrane stack occurs and this is easily identified by monitoring the reduction in the flow of water, build-up of pressure, reduction in the current density (amperage), the voltage drop through groups of cellpairs, reduction in desalting. In such cases the opening of the stack and the manual cleaning of the membranes as well as CIP have to be carried out in order to re-establish the performance characteristics of the plant.

8.9 The operating experience on the EDR plant at Grootvlei Power Station was positive enough to consider its application at the Tutuka and Lethabo Power Stations for the concentration of the cooling water blow-down.

9. ACKNOWLEDGEMENT

The autors wish to thank the Water Research Commission and the Electricity Supply Commission for permission to present this paper.

BASIS FOR CALCULATIONS:

1. Feed water is cooling water at 20 concentrations, after side-stream treatment, and contains 1 047 mg/l TDS.
2. EDR water recovery is 80 % and the product contains 226 mg/l TDS.
3. Cost of electricity within the power station is 1,65 c/KWh.
4. Electrical power consumption is 1,2 KWh/m^3 product for the EDR plant plus 0,4 KWh/m^3 product for the transfer of the different water streams to and from the EDR plant.
5. Cost of Vaal water, containing 226 mg/l TDS is 35 c/m^3.
6. The cost of cooling water side-stream treatment is not included.
7. PV present value calculations are based on 30 years life span of the plant, 14 % discount rate and 12 % inflation rate.
8. EDR plant is operating 24 h/d, 365 d/y at 90 % availability.
9. EDR membrane replacement is 20 % per year.

ELECTRODIALYSIS (ED) + ELECTRODIALYSIS REVERSAL (EDR)

The S A Institution of Chemical Engineers Symposium

"LIMITING LIQUID DISCHARGES FROM LARGE
INDUSTRIAL FACILITIES"

16th November 1982

SUMMARY

Electrodialysis is a process that has been available for the demineralisation of brack and waste water streams since the early 50's. The development of polarity reversing electrodialysis in the early 70's made the process far more economically competitive owing to the reduced feed pretreatment requirements, increased water recovery rates and improved tolerance to fouling. Advances in engineering with respect to automation, materials of construction and improved ion exchange membrane characteristics allowed the process to compete industrially on a large scale during the last decade. Electrodialysis Reversal has been demonstrated as a technically viable and competitive process for the limitation of discharges from industrial complexes and is poised to become applied on an even wider scale during the 80's.

ELECTRODIALYSIS (ED) + ELECTRODIALYSIS REVERSAL (EDR)

1.0 INTRODUCTION

Despite the fact that S A engineers and chemists made a major contribution to the advancement of Electrodialysis (ED) technology during the 1950's (1) comparatively little work was done in S A since then, apart from small scale research work at the CSIR and NIWR. Technological advances of the reverse osmosis (RO) process naturally led to this process becoming widely accepted for desalting purposes and by 1974 the total installed water desalting capacity of RO overtook ED. (2)

The birth of RO and its sustained growth naturally created severe competition for the classical undirectional ED process. Under competitive pressures the leading ED firm situated in the U S A concentrated on technical innovation as a means of improving its share of the desalting market. Manual polarity reversal was known to remove scale buildup on ion exchange membrane surfaces (1). This fundamental principle was extended by full automating the reversal of polarity and the sequential changeover of concentrate and diluting streams, thus establishing the first fully symmetrical membrane reversal process - now called electrodialysis reversal (EDR) (3).

Indeed the application of this technique can be regarded as a major breakthrough for electrodialysis as it resulted in several important commercial benefits.

- Ability to operate at traditional recoveries (±75%) without any chemical feed.
- Ability to operate at high recoveries (±90%) with relatively small amounts of chemical addition.
- Longer membrane life
- Reduced pretreatment requirements
- Improved resistance to membrane fouling
- Wider range of technological applications.

Prior to examining the potential that EDR has for limiting liquid discharges from large industrial facilities it will be useful to examine briefly the principles of electrolysis, electrodialysis and electrodialysis reversal.

2.0 PRINCIPLES OF ELECTROLYSIS, ED + EDR

Most common inorganic salts when dissolved in water will dissociate into cations and anions. Figure 1A illustrates the dissociation of sodium chloride in water. In figure 1B a d.c. potential has been applied across the electrodes immersed in the solution, thereby causing the anions to move toward the positive electrode and the cations to move toward the negative electrode. This is the well known principle of electrolysis which is widely applied in the manufacture of chlorine.

2 / ...

If membranes having selective permeability to cations and anions respectively are introduced between the two electrodes to form three water-tight compartments (figure 2A), followed by the application of a d.c. current across the electrodes, then the central compartment will be demineralised (figure 2B). Na^+ ions from compartment A cannot pass through the anion membrane into compartment B and likewise Cl^- ions from compartment C cannot pass through the cation membrane into compartment B. However, both Na^+ and Cl^- ions can pass through the cation and anion membranes respectively giving rise to the demineralisation in the central compartment, and concentration in the two end compartments.

Figure 3 respresents a multicompartment unit similar in principle to the commercial ED stack. Letter 'A' designates the anion membranes, letter 'C' the cation membranes, the +ve sign the anode and the -ve sign the cathode. Clearly the principle of operation of the multicompartment cell is similar to that previously illustrated in figure 2. In the case of ED the process continues indefinitely with the diluting and concentrating compartments performing the same function for the entire life of the installation. The first slide gives a clearer picture of the process which in this particular case shows the brine recycle loop.

Shown in slide 2 is a view of the most widely used commercial membrane stack - the Ionics Mark III. Electrodialysis membrane stacks exist today designed and assembled with the membranes stacked in either the vertical or the horizontal position. Differences in both membrane thickness and spacer flow patterns exist. One configuration which has seen limited use by Japanese and European suppliers is the thin membrane (± 0,2 mm) and the "sheet flow" spacer type. The other design which has been dominant over the past decade was developed in the U S A. In this configuration the tortuous path spacer with thicker more durable membranes (± 0,5 mm) are used. The latter design achieves a uniform hydraulic flow distribution across the face of the membrane and has thus proved the more successful in a variety of desalting applications. The third slide shows an exploded view of a cell pair which consists of a cation membrane, an anion membrane and two tortuous path spacers.

In EDR, when the d.c. polarity is reversed the direction of the flow ofions also reverses. The reversal takes place at regular preset intervals which is normally between 15 and 30 minutes. The stream which was the concentrate now becomes the dilute and vice versa. Automated changeover valves ensure that the product and brine streams do not contaminate each other at reversal. After the reversal the concentrations of both compartments are changing and are not at their steady state levels. For an interval of 1-2 minutes off-spec product is either recycled or wasted.

3 / ...

In both the case of ED and RO, which are unidirectional processes, there is a tendency for constituents which are capable of forming slimes and precipitates to be deposited at the membrane solution interface. Over a period of time this can seriously affect the membrane desalting performance.

However, in the case of EDR any tendency for scale buildup will be extremely short lived and after reversal scale and film will be purged away from the surface, dramatically improving the performance. The principle of scale removal is synonomous to the reversing heat exchangers used in the cryogenic industry for removal of carbon dioxide and water scale from low temperature surfaces.

Because the EDR process has this self cleaning characteristic it has emerged as a rapid growth desalting process and is now gaining ground in the treatment of different quality waters. By the last quarter of 1982 the EDR installed or contracted capacity has grown to over 250 000 m^3/day in a period of 8 years.. EDR has been commercially competitive for desalting waters with a TDS between 250 and 12 000 ppm. Further improvements in membrane technology and cell stack design are underway to widen the range of applications for both higher and lower TDS wastes.

3.0 EXISTING APPLICATIONS

3.1 General

EDR is certainly not the panacea to every industrialist's effluent problem. However, it can go a long way in solving a variety of problems where it is usually a partial rather than a total solution to eliminating waste discharges.

When reviewing any potential applications for EDR it is important that not only the process stream in question is examined, if this is a composite of streams emanating from several sources. Often the most cost effective solution could lie in the treatment of any one or more of the separate streams rather than the overall combined stream.

3.2 Boiler Feed Water Preparation

In this regard EDR is fulfilling a useful role for the predemineralisation of boiler feed water.

Demineraliser wastes from conventional ion exchange plants are not only composed of a concentration of the salts that were in the original feed, but in addition contain the salts of the neutralised regeneration chemicals which are often 3-5 times greater by weight than the original salts in the feed.

4 / ...

By introducing EDR as a primary demineralising step the effluent salt load will be reduced significantly. However, on waters with a TDS higher that 300 ppm the capital and operating costs of the EDR plant can be justified on the savings in regeneration chemicals alone, without inclusion of credits arising from reduced mineral discharge. This is particularly true when considering new demineralisation facilities or the extension of existing facilities which have become a bottleneck as a result of the deterioration of the feedwater quality or increased demand.

3.3 Whey Desalination and Lactose Removal

The growth of the cheese manufacturing industry and the progressive tightening of restrictions on the disposal of whey, motivated dairies to seek new outlets for products which could be recovered from whey. Owing to the nutritional value of whey it can be used as animal feed for limited local markets. Normally transport costs prohibit its consumption further afield and excess whey was discarded.

Whey is a dilute solution containing salt, lactose, protein and fat. The salt (or ash as it is commonly referred to) can be removed using an electrodialysis stack similar to that used in water desalting. This salt removal is only a partial solution to recovering and producing deashed whey. The total process normally involves solids concentration, pH adjustment and clarification, electrodialysis followed by spray drying to produce a free flowing saleable product of high nutritional value. Deashed whey is used as a major component in infant food formulaes.

3.4 Groundwater restoration for In-situ Mining

In the USA where in-situ mining of uranium has been practised, increased emphasis has been placed on improving water conservation as well as restoration of aquifier waters. A commercial sized EDR plant has been used for pilot restoration work (8) where it has proven its ability to treat waters with both high calcium bicarbonate and sulphate levels in the feed. Despite relatively high levels of both these components in the feed and the supersaturation of calcium sulphate in the brine loop, scaling was minimised due to polarity reversal while cleaning was easily and effectively done using a standard clean in place circuit.

5 / ...

General data taken from the report by Garling (8) (figure 5) shows the demineralisation potential of EDR for this typical mine water. Following the successful demonstration for this application, a further commercial sized plant of 1000 m^3/day has been installed for aquifier restoration in Texas.

3.5 Calcium Sulphate Concentration above supersaturation

At the same time work was undertaken at the OWRT test facility in New Mexico where a commercial sized EDR plant, the Aquamite X was used to desalt a high $CaSO_4$ bearing brine stream.

It has been demonstrated that EDR could be used without any chemical addition up to the point where scaling occurred, at a $CaSO_4$ saturation of 230% and a Langelier Index of 2.45. Above these limits it was found necessary to introduce sodium hexameta phosphate (SHMP) and acid into the brine stream. Trouble free operation has been shown over a 5000 hour test period with water recoveries of up to 93,5% and $CaSO_4$ saturation levels of 440%.

The commercial possibilities for the treatment of S A minewater is a natural extension of the success already gained. This applies to all underground waters whether these be from coal, gold or uranium and where the waters are notably high in sulphates due to the oxidation of pyrite. Undoubtedly careful attention needs to be given to the pretreatment of these waters prior to demineralising with EDR.

3.6 Desalting of Sewage Effluent

In September 1982 the first commercial sized EDR plant for desalting water arising from the Municipal Sewage Treatment plant was commissioned at Dubai. The effluent is blended with city water in the first of four maturation ponds, thus reducing the oxidation requirements at the inlet of the subsequent chlorination stage. After chlorination, carbon slurry and ferric sulphate is added upstream of two clarifiers. The overflow from the clarifiers passes through two filters in series containing sand and activated carbon before reaching the EDR feed tank. This is certainly the most complex of any pretreatment system used in conjunction with EDR.

The feedwater with a TDS in excess of 2000 ppm is reduced to a salinity of approximately 600 ppm. Longer term operating results over varying load conditions will be compiled in the future. Start up analysis is shown in figure 6.

6 / ...

4.0 POTENTIAL APPLICATIONS

To cover all potential applications for EDR and to give a broad outline of each is beyond the scope of this paper. However, I will mention only a few and would gladly answer questions on these or other related subjects.

a) Cooling Tower Blowdown (7)
b) Boiler Blowdown
c) Plating Bath effluents (5)
d) Concentration of metallurgical plant effluents to produce a concentrate suitable for recovery and a product water suitable for recycle (5)
e) Concentrating dilute saline streams.
f) Reduce nitrogen (NH_4) loading from fertilizer factories (6)
g) Removal of organic acids.

The example given above demonstrate the wide variety ofpotential applications for ED and EDR. A good account is given in the references (5) and (6) by Messrs Schoeman and Botha.

5.0 LIMITATIONS OF EDR

Many industrial effluents are unique and may contain components which could reduce the efficiency of EDR. It is recommended that the Iron (Fe^{++}) and Manganese Mn^{++}) levels be kept below 0,3 and 0,1 ppm respectively. Aromatic based anion resins require a zero residual chlorine level although aliphatic resins will operate over long periods at chlorine levels of 0,3 ppm and can be shock chlorinated at levels up to 10 ppm for control of biological growth.

6.0 CONCLUSIONS

EDR minimises slime or inorganic salt scale by utilising polarity reversal and where unpredicted scaling cannot be controlled or removed by the "clean-in-place" circuit the stacks may be disassembled for individual cleaning of the membranes. As EDR is suitable for concentrating salts from dilute solutions it can be used to reduce effluent volumes prior to final disposal or it may be used to recover both water and potentially valuable materials.

Electrodialysis Reversal has been demonstrated as a technically viable and competitive process for the limitation of discharges from industrial complexes and is poised to become applied on an even wider scale during the '80s.

DESALINATION: A SOUTH AFRICAN PERSPECTIVE

C.F. SCHUTTE

ELECTRODIALYSIS

7.1 Introduction

Desalination by electrodialysis (ED) is based on the fact that most dissolved salts in water are ionic in nature and that these electrically charged ions are attracted by opposite electrical charges. To utilize this phenomenon to desalinate water, membranes which will allow cations or anions - but not both - to pass are placed alternately between the electrodes. By this arrangement concentrated and diluted solutions are formed in the spaces between alternating membranes.

The present day electrodialysis industry came into being in the 1950's when sheet membranes made from ion-exchange resins were used to demonstrate the desalination of brackish waters. A significant event in the early days of the ED industry was the construction of an 11 Ml/d plant for desalinating underground mine water in the Orange Free State. However, before the plant was fully operational the need to desalt the water fell away and the project was stopped.

Since 1945 when the first ED unit was sold up to 1975 installed ED capacity totalled almost 100 Ml/d. In the early 1970's the Electrodialyses Reversal (EDR) process was developed and from 1975 onwards very few conventional ED plants were installed. EDR is inherently less prone to scale formation and other fouling (than conventional ED) since scale is dissolved and fouling material flushed from the system when the polarity (and the flow direction) are reversed.

7.2 Operating Principles

The EDR flowsheet utilizes a standard ED array of alternating cation and anion membranes. It operates on the same basic principles as the standard electrodialysis unit, except that both the product and the brine cells are identical in construction. At intervals of 3 to 4 times per hour, the polarity of the electrodes is reversed and the flows are simultaneously switched by automatic valves so that the product cell becomes the brine cell and the brine cell becomes the product cell. The salts are thus transferred in opposite directions across the membranes after polarity reversal.

Figure 7.1 gives a schematic illustration of the process (USAID 1980) and figure 7.2 shows the basic components of an electrodialysis unit (USAID 1980).

Following the reversal of polarity and flow, the product water is discharged until the cells and lines are flushed clean and the desired water quality is restored. This takes approximately 1 to 2 minutes. The reversal process aids in breaking up and flushing out scale, slimes, and other deposits in the cells. This automatic cleaning action eliminates the need to continuously add acid and/or polyphosphate to prevent scale formation in the electrode compartments. Scaling and fouling are also prevented by in-place automatic chemical cleaning systems with solutions containing sodium hydroxide, hydrochloric acid, sulfuric acid; or sodium chloride.

When polarity reversal and in-place cleaning are insufficient, and scaling does occur the stacks must be disassembled, cleaned, and reassembled. The individual spacers and membranes can be soaked in appropriate cleaning solutions and are rugged enough to be hand-scrubbed if necessary. In many cases when stack disassembly is necessary, only a portion of the membranes need to be cleaned. The membranes to be cleaned can usually be identified by taking resistance measurements on individual membranes, or groups of membranes while the unit is operating. The reversal of flow and polarity in the stacks greatly extends the intervals between the rather time-consuming job of stack disassembly and reassembly. The overall result is reduced maintenance time.

Many of the substances which make up the total dissolved solids in brackish water are strong electrolytes. When dissolved in water they ionize; that is, the compounds dissociate into ions which carry an electric charge. Typical of the ions in brackish water are Cl^{-1}, Na^{+1}, HCO_3^{-1}, Mg^{+2}, SO_4^{-2}, and Ca^{+2}. These ions tend to attract the dipolar water molecules and to be diffused in times, fairly evenly throughout a solution.

If two electrodes are placed in a solution of ions, and energized by a battery or other direct current source, the current is carried through the solution by the charged particles and the ions tend to migrate to the electrode of the opposite charge.

If alternately fixed charged membranes (which are selectively permeable to ions of the opposite charge) are placed in the path of the migrating ions, the ions will be trapped between the alternate cells formed.

Note 1: A positively fixed charge (anionic) membrane will allow negative ions to pass, but will repel positive ions.

Note 2: A negatively fixed charge (cationic) membrane will allow positive ions to pass, but will repel negative ions.

If this continued, almost all the ions would become trapped in the alternate cells (concentrate cells). The other cells, which lack ions, would have a lower level of dissolved constituents and would have a high resistance to current flow.

The phenomenon illustrated above is used in electrodialysis to remove ions from incoming saline water on a continuous basis. Feedwater enters both the concentrate and product cells. Up to about half of the ions in the product cells migrate and are trapped in the concentrate cells. Two streams emerge from the device: one of concentrated brine and the other with a much lower concentration of TDS (product water).

7.3 Elements of an EDR Unit

7.3.1 Pretreatment

The requirements for pretreatment in electrodialysis are somewhat less stringent than for reverse osmosis due to the nature of the process. The electrodialysis reversal process reduces the necessity for chemical pretreatment for many applications, but removal of suspended solids, iron and manganese is still critical to avoid fouling and/or other problems with the system. Pretreatment may still be necessary to produce feed water with : Iron 0,3 mg/l; Manganese 0,1 mg/l; Turbidity 2 JTU; H_2S 0,3 mg/l; no free chlorine. (New types of membranes are tolerant to small quantities of chlorine).

Pretreatment is often necessary to prevent microbiological growth on the inner surfaces of the membrane stack. As in the reverse osmosis process, these surfaces provide a place for them to metabolize in the feedwater. A chlorination-dechlorination step is used if the problem is of sufficient magnitude otherwise, the organic slimes are removed in a cleaning step. The dechlorination step is necessary to protect the membranes from continuous exposure to free chlorine.

7.3.2 DC Power Supply

This is usually a rectifier which converts the alternating current to a direct current electricity supply.

7.3.3 Membrane stack

The stack includes the electrodes, membranes, spacers and necessary plumbing.

(i) Membranes : The membranes are flat sheets, usually made of a plastic film formed on a fabric backing to provide strength with ion transfer sites added to the membranes to give each type the required selectivity to pass either anions or cations.

Cation membranes generally consist of cross-linked polystyrene that has been sulfonated to produce fixed ionic charges in the membrane. Anion membranes have quaternary ammonium groups fixed in a similar cross linked polymer. A new generation of aliphatic anion membranes are less prone to organic fouling than the older aromatic membranes.

In water the fixed ionic groups ionize to form mobile counter= ions which readily exchange with ions of the same charge in the water solution under an applied direct electric current. Mem= branes come in a variety of sizes, depending on the manufac= turer and the application. A typical full scale size is 46 by 102 cm. The thickness of the membrane depends on the applica= tion. Thicker membranes usually have greater strength, in= creased erosion resistance, and longer life, whereas thinner membranes have lower electrical resistance and hence reduced energy requirements. Typically, membranes are about 0,56 mm thick.

The structure of membranes can also be varied to suit different conditions; for example the water content can be varied making the membrane more or less ion permeable.

The following characteristics are required from an ED membrane: thermal stability; mechanical strength, resistance to chemical and biological degradation; dimensional stability; ionic selectivity; low cost; low resistance.

(ii) Spacers : The spacers separate the membranes and provide a pathway in the cell for the water flow. Cells are made up of two membranes with a spacer between and are stacked with alter= nating concentrate and dilute cells. The number of stacks, stages and electrodes are designed to suit specific circumstan= ces and requirements such as feed water quality and required product quality.

(iii) Electrodes : One pair of electrodes is required for each electrical stage. The electrodes are generally constructed of niobium or titanium with a platinum coating.

7.3.4 Circulation pumps

These are used only for circulation of the water through the stack. The head loss varies with the construction of the stacks, number of stages, etc, but generally a pressure of about 350-500 kPa is required compared to the 1,5-2,5 MPa required for reverse osmosis. Because of the reduced pressures the connecting piping, valves, etc, can be made from standard plastic pipe and fittings at lower cost (compared to stainless steel, etc) and with high resistance to corrosion in a saline environment.

7.4 Process characteristics

7.4.1 Power consumption

Electrical power is used for pumping water through the system as well as for the transfer of ions through the membranes. Overall energy usage is proportional to the amount of dissolved solids removed. Stack power usage amounts to about 0,7 kwh/m^3 product per 1000 mg/l of dissolved solids removed while pump power usage ranges from 0,5 to 1 kwh/m^3 product. Power losses amount to about 5% of total usage.

This gives a total power consumption of
1,3 - 1,9 kwh/m^3 to remove 1000 mg/l of TDS
2,0 - 2,6 kwh/m^3 to remove 2000 mg/l of TDS
3,5 - 4,1 kwh/m^3 to remove 4000 mg/l of TDS
as compared to 2 - 3,2 kwh/m^3 for brackish water desalination by reverse osmosis.

EDR is therefore energywise highly competitive to reverse osmosis for the desalination of brackish waters with TDS concentrations of up to about 2000 - 3000 mg/l.

7.4.2 Dissolved solids removal

A single electrodialysis hydraulic stage can remove from 40 to 60% of the entering total dissolved solids depending on feedwater characteristics. Further removal of dissolved solids requires that two or more stages be used in series. More than one hydraulic stage can be built into one stack and more than one stack can be used in series. Any required level of dissolved solids removal can therefore be achieved by adding hydraulic stages in series, each of which will remove about 40-60% of the incoming TDS to that stage. However, each additional stage will increase capital and operating costs and therefore the plant design usually is a compromise between required product water quality and economic considerations.

The extent to which feedwater is desalinated in each stage depends on the residence time in the stage and the current density. Current densities are kept as high as possible to improve desalination. The actual current flow is limited by the high electrical resistance when the ionic concentration of the water is sharply reduced.

7.4.3 Process efficiency

EDR Desalination of brackish waters with dissolved solids concentrations lower than about 3000 mg/l of dissolved solids can be done on a cost competitive basis compared to reverse osmosis (depending on water quality and ionic composition). Electrodialysis membranes are resistant to chemical and microbiological attack and have average lifetimes of longer than 5 years. The membranes can be cleaned chemically in the stack or can be removed and cleaned mechanically.

The EDR process can achieve very high water recoveries without elaborate pretreatment even with feedwaters containing high concentrations of scale forming substances such as calcium sulphate. It has been demonstrated that an EDR plant can desalinate waters containing calcium sulphate at 250% of the saturation limit without any chemical feed and at higher than 400% with acid and sodium hexametaphosphate addition to the brine side (Elyanow 1981).

Only ions are removed from the feed water and therefore organic material is not removed to any significant extent and thus remains in the product water. In water reclamation applications where organic material in the product is important EDR therefore does not have the same advantage as reverse osmosis which removes most of the organic material in the feed water.

7.5 Applications

Electrodialysis and in particular electrodialysis reversal (EDR) is applied almost exclusively for the desalination of brackish waters for domestic and industrial use. The cumulative installed capacity of 228 EDR plants in 1980 was 150 Ml/d (Techno-Economic Services 1981).

EDR has also found application for the production of low TDS process water such as for printed circuits in the computer industry and also for boiler feed water. In these applications EDR is usually combined with another demineralization process, typically ion exchange to produce very low TDS waters. (Highfield 1980).

Research on the application of EDR for the desalination of cooling water blow down at power stations and for desalination of underground mine waters is currently in progress in South Africa.

--- oOo ---

TABLE 11.3

BRACKISH WATER DESALINATION

Reverse osmosis (RO) : Feed 2000 - 5000 mg/l : 80% recovery,
Electrodialysis reversal (EDR) : Feed 1800 mg/l, 3 stages

Plant capacity	3 800 m^3/d		18 900 m^3/d	
	RO	EDR	RO	EDR
Installed equipment cost $\$/m^3/d$	158	328	138	303
Total capital cost $\$/m^3/d$	318	531	254	464
Water cost $\$/m^3$				
Fixed capital charge @ 18%	0,16	0,26	0,12	0,23
Operation and maintenance	0,08	0,07	0,05	0,04
Membrane replacement	0,04	0,05	0,03	0,03
Electricity @ \$0,05 kwh	0,10	0,05	0,10	0,05
Total water cost $\$/m^3$	0,38	0,41	0,31	0,35

Total desalinated water costs for electrodialysis reversal for a 18 900 m^3/d plant vary from $\$0,31/m^3$ to $\$0,42/m^3$ depending on the chemical composition of the feedwater which in turn determines the water recovery possible (80-87%) and the number of stages required for a specific production and desalination duty. The figures given in table 11.3 are for one type of feedwater and a product quality of 500 mg/l TDS.

WARNING

1. Caution should be exercised when using these cost data.
2. These costs are computed for basic desalination facilities in the USA. These costs include no storage capacity and allow for only fundamental feedwater development and brine disposal. If storage capacity is added and/or more complex feedwater or brine facilities are required, overall project costs can significantly increase. This is especially true with brackish water facilities. Construction in locations outside the USA can also add to the overall cost. Actual costs of up to 300% (or more) of those shown on this figure (especially at lower capacities) would not be unusual for projects in many developing areas.

IONICS

IONICS, INCORPORATED

PROCESS SYSTEMS

The Ionics Aquamite 100 Electrodialysis Reversal (EDR) Plant producing predemineralised water for the Escom Kriel Power Station. The plant is the largest of its kind in the southern hemisphere and the largest desalting plant in South Africa.

While EDR is a relatively new technology in South Africa, this process has been used successfully throughout the world for the demineralisation of various waters. The process has also been demonstrated for the demineralisation of cooling tower blowdown at the Grootvlei Power Station where a pilot programme has been underway for over a year. While the process has many advantages over other membrane processes, undoubtedly two of its main features are its resilience to operator error and membrane fouling, both of which determine the cost effectiveness of all membrane processes. These two factors are all too often not quantified during the technical and commercial feasibility of demineralisation processes.

AQUAMITE®

EDR Systems for Water Demineralization

EDR Systems — Electrodialysis Reversal for Reliability in Water Treatment

Ionics, "The Water Company", manufacturers and supplies a comprehensive line of water and wastewater treatment systems and instruments featuring unique technology developed in the Company's laboratories.

Ionics began in the water business with the invention of the ion transfer membrane in 1948 which resulted in the development of the classical ED (electrodialysis) process. In 1954, the ED process was introduced commercially to demineralize brackish waters in Saudi Arabia.

The New EDR (electrodialysis reversal) process was developed in the early 1970's to solve operating and maintenance difficulties encountered when injecting acids and chemicals into the system to control scaling. The elimination of chemical feeds and low-cost automatic operation earned rapid acceptance for the EDR process.

Today, over 500 EDR systems, the largest with a capacity of 24,000 cubic meters per day (6 million gallons), demineralize water for industrial and municipal applications in over 25 countries around the world.

The Aquamite

The Aquamite combines high efficiency membrane stacks with skid mounted modules containing electric power and automatic control systems, low pressure centrifugal pumps and corrosion proof plastic piping. Completely assembled systems are factory tested to meet the requirements of each project resulting in low installation costs, rapid commissioning, and high on-line reliability.

Ionics' total Aquamite spectrum is composed of seven Aquamite systems with production capacities from 2 to 4,000 cubic meters per day (500 to 1 million gallons). Multiple units are used to systems over 4,000 cubic meters per day.

Features

- Fully automatic — simple operation
- Water recoveries up to 95%
- Salt removal up to 99%
- Lowest operating and maintenance costs
  - Zero chemical feed for normal operation
  - Polarity reversal for automatic scale control
  - Proven membrane life up to 10 years
  - Low pressure operation
  - Low electric power
- Feedwater salinities from 100 to 12,000 ppm TDS
- Product water purity to 10 ppm TDS
- Ambient temperatures up to 55°C (131°F)
- Feedwater temperatures up to 45°C (113°F)

Applications

- **Drinking Water**
  - Towns and Villages
  - Hotels and Hospitals
  - Construction and Military Camps
- **Boiler Feed and Cooling Tower Water**
  - Power Plants
  - Refineries
  - Petrochemicals
- **Process Water**
  - Cement Manufacturing
  - Food and Beverage Processing
  - Metals Industry
- **Ultrapure Water**
  - Electronics
  - Pharmaceuticals
  - Biomedical
- **Agricultural Water**
  - Poultry Farms
  - Greenhouses
  - Hydroponics
- **Water Re-use**
  - Municipalities
  - Mining
  - Industry

Ionics Capabilities

- Research and Development — Advanced Membrane Systems
- Design and Engineering — Water Treatment Systems
- Manufacturing — Membranes/Equipment/Systems
- Turnkey Construction — Total Responsibility
  - Water treatment systems
  - Civil Works
  - Electro-mechanical installation
  - Commissioning

A NEW TECHNOLOGY FOR ESCOM

PROCESS SYSTEMS AWARDED THREE DESALTING CONTRACTS

While much publicity has been given to the reverse pumping of the Vaal River, relatively little has been mentioned of yet another project important to the operation of the Kriel Power Station, which is capable of generating nearly a seventh of Escom's electricity output.

Process Systems in conjunction with their principals, Ionics Incorporated of Boston, U.S.A., have supplied, delivered, erected and commissioned an Electrodialysis Reversal (EDR) plant in a record time of 12 weeks. Such a tight programme has only been possible through the co-operative efforts of all the suppliers and subcontractors. The contractor's achievements are further highlighted by the fact that this plant is the largest of its kind in the southern hemisphere and the largest membrane desalting plant in South Africa.

The Kriel Power Station was designed to take water from the Usutu River system which has a much lower salinity level than that of the Vaal River. The Ionics EDR process is being used to reduce the Vaal River salinity to a level lower than that of the Usutu River, thus enabling the station to use its existing demineralisation plant for the production of boiler feedwater. The EDR plant at Kriel Power Station will enable the station to operate at full capacity on Vaal water supply.

While EDR is a relatively new technology in South Africa, this process has been successfully used throughout the world for the demineralisation of brack waters. Escom engineers visited several operating plants overseas to evaluate the suitability of this technology, and a pilot plant programme has been underway at the Grootvlei Power Station for over a year.

The Van Eck power station, operated by SWAWEK in S.W.A., took the lead in the commercial utilisation of EDR a year ago. Like Escom, SWAWEK were faced with a deteriorating water quality due to the prolonged drought in S.W.A. The Van Eck plant has been operating successfully since its commissioning in November 1982.

The technology has tremendous potential in South Africa for numerous applications including:

- Pre-demineralisation of Boiling Feedwater.
- Preparation of Potable Water from Brack Water.
- Desalting of cooling tower blowdown, enabling recycle.
- Desalting of mine waters.
- Desalting certain effluents prior to recycle.

While the process has many advantages over other membrane processes, undoubtedly two of its main features are its resilience to operator error and membrane foulings, both of which determine the cost effectiveness of all membrane processes. These two factors are all too often not quantified during the technical and commercial feasibility of demineralisation processes.

Escom has placed another contract with Process Systems for the predemineralisation of Rand Water Board water for Klip Power Station. This new plant is cost effective based on the saving of chemicals used for normal regeneration of the existing ion exchange plant. A further benefit to Escom is the reduction in the amount of effluent leaving the works.

Both the Water Research Commission and the National Institute of Water Research have been instrumental in the introduction of the new technology to South Africa. Through the foresight of these two bodies, evaluation of the technology was in progress a long time prior to the current water problems. Indeed, they can be commended for their efforts in finding yet another of many solutions to the South African water problem.

PACKAGED ELECTRODIALYSIS PLANTS FOR WATER DEMINERALIZATION

The AQUAMITE V employs the proven process of electrodialysis (ED) to provide from 15,000 to 30,000 U.S. gallons per day (USGPD) of fresh water from brackish water, or very pure industrial process water from normal water supplies. In the ED process, the water to be demineralized is pumped at low pressure (30 to 60 pounds per square inch) between special plastic membranes and emerges as pure product water. Within the membrane assembly (called a membrane stack) DC electric current drives the salt and mineral particles, called ions, through the membranes to a concentrated waste water stream.

The AQUAMITE system can operate on feed waters up to 110°F and withstand pH ranges from 1.0 to 13.0. No chemicals are required for normal operation of the plant, thus eliminating the historical economic and operational problems associated with accurate dosing, equipment corrosion and local supply of hazardous and expensive materials.

The AQUAMITE system employs electrical Polarity Reversal in place of continuous chemical feed for control of scaling and membrane fouling substances. This unique process, coupled with occasional use of the Clean-In-Place (CIP) treatment system minimizes membrane stack maintenance problems. Membrane stack cleaning by stack disassembly offers a third maintenance option to maximize plant efficiency under extreme operating conditions.

Widely flexible design options allow the AQUAMITE to provide water over a broad range of product purities and capacities. This flexibility is achieved by staging of the membrane stacks. In general, increasing the number of stages increases product purity and reduces flow. Also, water temperature increases improves salt removal rates (see Operating Specifications table — back page).

The AQUAMITE consists of a membrane stack or stacks and a rugged steel skid containing the DC power supply/control unit, feed water filter, pumps, valves and other hydraulic equipment. An AQUAMITE V-2 has two 18 x 20 inch membrane stacks while the model V-1 has one. The V-2 therefore has twice the product capacity of the V-1 under the same operating conditions. Optionally, an 18 x 40 inch membrane stack may be used. If product water requirements or feed water composition changes, membranes or membrane stacks can be added in the field or staging changes can be made to solve the problem.

The AQUAMITE ED plant is tailored to each individual application while maximizing standard design components. The use of standard designs reduces capital costs and allows for rapid delivery of AQUAMITE units. All PVC piping and bronze pumps give maximum protection against corrosion and product contamination.

Details of feed water characteristics and product water requirements determine recommended membrane stack areas, staging and any special pretreatment requirements. Pretreatment would normally be recommended for waters containing free chlorine, iron over 0.3 ppm, hydrogen sulfide over 0.3 ppm, turbidity above 2.0 JTU, or manganese over 0.1 ppm. A completed "Water Questionnaire" and analysis of your water will enable IONICS to prepare an engineering study for your consideration.

The AQUAMITE unit is typically housed in a structure that will minimize extreme exposure conditions. The engineering drawings provided show layouts and connections so that the skid and membrane stacks can be easily installed. Three hydraulic lines are required: feed water, product water, and concentrate water. A single power connection at the DC power supply/control unit panel completes the installation.

In automatic operation, a low pressure pump introduces feed water through a cartridge filter to alternate passages in the membrane stack in series. Flow through each stage of the unit. DC power is applied though the membrane stack with current and voltage outputs monitored on the digital display. Another low pressure pump circulates concentrate water on a rotate basis to alternate water passages adjacent to the feed water passages in the membrane stack with a calculated fraction sent to waste. The DC power supply and pumps are activated by signals from level controls in the product water storage tank.

At a fixed point in time (about three to four times per hour) Polarity Reversal occurs, automatically reversing the electrical polarity of the stack and by means of motor operated valves reversing the product water, concentrate and electrode streams. This reversal purges membrane and electrode surfaces of scaling and fouling materials which may have deposited during the cycle. Product water purity is continuously monitored with a conductivity controller which automatically diverts "off spec" water to drain in case of system malfunctions. The polarity status of the membrane stack is indicated by lights on the control module.

Automatic controls shut down the unit in case of high temperatures in the DC power supply/control unit or high/low hydraulic pressures.

The following table shows typical operating specifications of the AQUAMITE V-2 (two membrane stacks). The Model V-1 (with a single stack) produces about one half these flows. Actual operating specifications depend on exact feed water composition, temperature, and stack design and are given only with formal quotations based on complete information on your water. To meet specific economic or site requirements, designs can often be adjusted to achieve either lower energy consumption or higher water recovery or greater demineralization.

The table covers waters of assumed 75% sodium chloride type in the most commonly encountered range of 1500 to 3500 parts per million total dissolved solids. Waters of lower total solids can be treated at lower energy consumption, and waters of higher total solids — up to about 7000 ppm — can be treated at greater energy and lower production.

FEED WATER TOTAL DISSOLVED SOLIDS (TDS)	1500 (ppm)		2500 (ppm)		3500 (ppm)

EVALUATION OF ELECTRODIALYSIS FOR PROCESS WATER TREATMENT FOR IN SITU MINING

R. A. Garling

UMC Teton Exploration Drilling, Inc.
3030 Energy Lane
Casper, WY 82601

INTRODUCTION

Since the infancy of in situ uranium mining, a growing number of hydrometallurgical processes have been incorporated into pilot and commercial scale flowsheets. Although initial design efforts were geared toward maximizing uranium recovery and minimizing plant and wellfield flow circuit maintenance, recent emphasis has shifted to improved means of water conservation and aquifer restoration. As mining units approached depletion, evaporation ponds reached minimum freeboard, and state and federal agencies demanded proof of groundwater restoration, processes including mixed bed and conventional ion exchange, reverse osmosis and electrodialysis were adopted by the industry. These units served the additional function of reducing process bleed flows during mining in states where the deep disposal well permitting ice remains unbroken.

This report concerns the use of electrodialysis as an alternative to the more conventional processes used in in situ mining. In addition to a brief history and description of the process, a comparison to reverse osmosis and operational data derived from testing an Ionics, Inc. 1.31×10^{-3} m^3/s (30,000 gallon/day) unit at the Teton-Nedco Leuenberger Research and Development pilot will be presented.

HISTORY

Commercially practicable electrodialysis was contingent upon the development of synthetic ion exchange membranes in 1940's. In 1952, Ionics Inc. demonstrated that the process was amenable to the treatment of salt and brackish water and, in 1954, made their first commercial sale. The following decade saw several major electrodialysis unit sales which were generally targeted for use on private or municipal potable water treatment. Major increases in membrane desalting unit capacities, facilitated by technological advances in the reverse osmosis industry, were noted during the 1970's. The development of polarity reversing electrodialysis equipment which reduced feed pretreatment requirements, increased water recovery rates, and simplified unit operation, kept Ionics Inc. competetive in the water treatment industry. Engineering advances which incorporated automated equipment, non-corrosive construction materials, and improved ion exchange membranes allowed the electrodialysis process to compete in industrial waste treatment among other commercial markets.

PROCESS AND APPARATUS DESCRIPTION

The electrodialysis process utilizes direct electrical current passed across a stack of alternating cation and anion selective membranes in order to achieve an electrochemical separation of ionized materials in an aqueous solution. The membrane stack has the appearance of a plate and frame filter press and auxilliary equipment includes solution pumps, electrically actuated valves, filters, piping and a direct current power source. The ion separation membranes are thin sheets of synthetic cation or anion selective resins. Attaching sulfonate or quaternary ammonium groups to the cross linked copolymer structure determines the ion selectivity of the membrane. The membranes are separated from each other in the stack by non-conductive spacers that house flow channels which route the flow tortuously and parallel to the membranes. Direct electrical current passing perpendicularly to the membranes and solution passages attracts cations toward the cathode and anions toward the anode (Figure 1). As the ions from the feed stream pass through the ion selective membranes, they become concentrated in the adjacent brine channel and are retained there by the combined attractive force of the electrode and the repelling force of the next membrane toward the electrode. Limiting factors on the degree of demineralization possible include chemical solubilities in the brine flow and the current density that will produce an unacceptable degree of polarization (Figure 1). Feed or brine solution treatment with complexing agents or acids has been successfully applied to prevent membrane scaling. Polarization can occur when sufficient current density is applied to dissociate water in the ion depleted region of the diluting compartments near the membrane surfaces. Significant polarization is evidenced by large electrical resistances across cell pairs and notable pH differences between diluting and concentrating streams. Limiting current densities have been increased in U.S. manufactured equipment by utilizing tortuous flow paths of relatively high linear velocities thereby promoting continous solution mixing. Energy consumption is due to separating electrolytes and solutions, oxidation and reduction reactions occurring in electrode compartments, overcoming electrical resistance, conversion from AC to DC power, solution pumping and auxiliary equipment actuation.

A major improvement to the basic electrodialysis process was applied in 1970 which resulted in frequent, automatic cleaning and descaling of membrane surfaces. The process, polarity reversal, incorporates alternating the cathode and anode on a periodic basis while exchanging product and brine flow channels via electrically actuated values. The reversal reduces the potential of stack plugging with $CaCO_3$ (calcite), $CaSO_4$ (gypsum), and colloidal materials and, in most waters, eliminates feed pre-treatment requirements. For approximately two minutes during and following the reversal, off spec. water is flushed to waste or reintroduced to the feed supply. The usual feed treatment on polarity reversing electro-

dialysis equipment (EDR) consists of filtration of particulates exceeding 10 μm (micron).

EDR COMPARED TO REVERSE OSMOSIS (R.O.)

The tool widely adopted by the ISL industry for process bleed reduction and groundwater restoration has been reverse osmosis (R.O.). R.O. units utilize excessive pressure exerted across semi permeable spiral wound cellulose acetate or hollow fiber polyamide membrane elements in order to reverse the natural osmotic process. The net result is similar to electrodialysis in that dissolved solids in feed water are concentrated into a reduced volume and relatively high "clean" water recoveries are noted.

There are several dissimilarities between the processes that suggest significant advantages to the EDR operator. Due to the microscopic pore size of the R.O. membrane, more chemical pretreatment and filtration is required than for the 1 mm flow channels in the EDR stack. Pre-softening or complexing EDR feed is not generally required and the membranes withstand silica scaling. ED membranes can be operated in the pH 1-10 range and exhibit stability to 316°K(110°F). R.O. membranes typically operate only in relatively small pH and temperature ranges. Materials of construction and maintenance costs are reduced for EDR due to the comparatively low feed pressures.

Perhaps the greatest single advantage to the EDR process is the stability and accessibility of the ion exchange membranes. Although ED and RO are similar in that the ion exchange media represents a large proportion of the initial capital cost of the unit, ED is unique because of the long term stability and maintainability of the membranes. Due to the low pressure feed and nature of the process, ED membranes do not suffer from the gradual compaction noted on R.O. membranes, and, as a result have demonstrated working lives in excess of 10 years. Formation of $CaSO_4$ scale that can result in RO membrane failure or plugging, is restricted in EDR operation due to polarity reversal and the commercial stack cleaning circuit. In contrast to R.O. membranes, ED membrane stacks may be physically disassembled and membranes may be individually scrubbed if scaling cannot be controlled or dissolved by the "clean in place" circuit.

Based on recent quotes from both RO and EDR manufactures, capital equipment costs are comparable and range from $175,000 to $250,000 for 1.26×10^{-2} m^3/s (200 gpm) units. Operating costs for EDR units have historically been equal to lower than comparably size RO units (when feed TDS remains below 5000 mg/l) and EDR feed pretreatment costs are typically lower.

PILOT TEST RESULTS

In late 1980, Teton Exploration and Ionics, Inc. initiated an agreement to perform a three month test with a commercially sized EDR unit on the ISL circuits at the Leuenberger pilot project located near Glenrock, Wyoming. An Aquamite V-H 1.31×10^{-3} m^3/s (30000 gallon/day) unit was received, installed, and operating continuously by 2-25-81. The dual stage unit was expected to produce 665 mg/l TDS water from a feed of 2650 mg/l with a product water recovery of ~80%.

Installation of the three ton, two piece unit required skid placement, plumbing unit feed, product and brine lines, and providing a peak 1.26×10^{4} J (35 KVA) power source. Electrical power was provided by the plant three phase diesel generators. Overall dimensions of the unit including reasonable maintenance clearance are 4.27 m (14 ft) x 6.1 m (20 ft) x 3.65 m (12 ft H).

The unit was to be tested on feed solutions comparable to those anticipated during the commercial operation including ion exchange barren effluent, mining zone restoration fluids, and impounded bleed.

Continuous operation began 2/25/81 with a 2.9 g/l TDS feed split from the ion exchange barren effluent stream. Due to the high initial Ca^{++} and HCO_3^- concentrations (0.25 g/l and 1.7 g/l respectively), pH adjustment of the feed flow to pH 5.8 to 6.0 with 35% hydrochloric acid was required to prevent $CaCO_3$(g) precipitation in the brine stream. As feed parameters reduced from the effect of field restoration, CO_2(g), introduced in gaseous form to the feed tank, replaced HCl as the pretreatment chemical.

Pretreatment costs during the test were $0.80/3785 L (1000 gal) for HCl and $0.91/3785 L (1000 gal) for CO_2(g). Although costs were ~14% higher for CO_2 (g) pretreatment, the addition was continued in order to prevent reintroduction of Cl^- ion to the restoring mining zones.

Ionics Inc., testwork indicated that membrane life would not be significantly reduced by feeding elevated levels of free chlorine which allowed recirculation of electrode compartment flows to the feed solution. This reduced brine flow from ~3.5×10^{-4} m^3/s (8000 gallons/day) to ~2.5×10^{-4} m^3/s (5700 gallons/day).

During the evaluation period, 1.25×10^{7} L (3.31×10^{6} gal) were fed at an average TDS of 2.35 g/l, and 1.02×10^{7} L (2.7×10^{6} gal) product at 0.35 g/l TDS and 2.24×10^{6} L (5.8×10^{5} gal) of brine were generated representing a salt rejection of 87.5% and water recovery of 81.5%. Chemical results from the final month of the test are presented in Table 1.

The unit operated 96% of the time available requiring only four cleaning cycles and no stack disassembly. Cleaning downtime was necessitated by operator error in neglecting to maintain flow to the feed tank during polarity reversals. The off specification water generated during the reversals continually enchances raw feed parameters by ~55%.

Routine operating costs averaged $1.02/3785 L (1000 gal) and broke down into pH adjustment chemicals ($0.86/3785 L (1000 gal)) and power requirements ($0.149/3785 L (1000 gal)). Approximately four manhours/day were required for data collection and unit operation and one manhour/day was needed for site analytical work.

A single day, 52,900 L (14000 gal) test was performed on feed from impounded bleed derived from an earlier groundwater restoration sweep. This test was designed to determine the feasibility of reducing water storage volumes by concentrating dissolved solids in a reduced volume and creating a product that met state surface discharge criteria. Test results indicated that the 3.1 g/l TDS feed could be split to provide 78% product water recovery at 0.66 g/l TDS. Additional pre or post treatment of the product to further reduce Ra-226 levels would be required to meet discharge quality.

Analyses performed over the duration of the test period showed a divalent ion rejection of 90.5% and a monovalent ion rejection of 84.8%. Radiometric and detectable trace elements showed feed to product splits equivalent to major constituents (Table 1).

In the Electrodialysis process, water flows between alternately placed cation (C) and anion (A) permeable membranes. A DC current provides the motive force for the ion migrations through these membranes. Salts in brackish water flowing through a "membrane stack" are removed or concentrated in alternate water passages.

In the Electrodialysis Reversal (EDR) system the classical ED process is used. However, at a fixed point in time (about 3 to 4 times per hour), Polarity Reversal occurs, automatically reversing the anode and cathode positions and, by means of motor operated valves, exchanging the "fresh product water" and "waste water" outlets from the "membrane stack". For a brief period (about 1 minute) product water is discarded to allow purging of fouling materials from the "stack".

Maintenance is simplified by controls located on the control panel. A flashing light indicates the need of a filter change. This is also indicated by pressure gauges on the hydraulic control panel.

The automatic Clean-In-Place (CIP) system for periodic (weekly to monthly) chemical flushing of the stack is activated from the control panel and this mode of operation is indicated by a panel light. The CIP system is used to remove stubborn residues from membrane surfaces if they occur. A fail safe system prevents wash water from contaminating product water.

Over the past 20 years, IONICS has learned to build electrodialysis systems to demineralize salty, brackish, hard, alkali, "gyp" or high nitrate waters economically under the widest range of climatic and geographic conditions.

IONICS has installed over 700 commercial electrodialysis plants ranging in size from 500 to 4,000,000 USGPD.

IONICS is the only manufacturer of membrane demineralization equipment that is a fully integrated single responsibility supplier.

IONICS provides a free water analysis of your sample as part of the initial proposal for your AQUAMITE application.

IONICS designs superior scale control systems that are exclusively available with the EDR process.

IONICS has learned to automate the overall AQUAMITE system to maximize on stream time and minimize operator attendance and maintenance.

IONICS manufactures and controls the quality of all membranes used in the AQUAMITE units.

IONICS builds equipment with components that stand up in tough applications including long life rugged membranes, corrosion resistant low pressure pumps, plastic piping and fail safe control systems.

IONICS modular AQUAMITE systems are skid mounted subassemblies to simplify field installation and minimize start up time and costs.

All AQUAMITE units are performance tested prior to shipment to maximize installation and start up efficiency.

IONICS maintains a world wide service organization, available for troubleshooting, start up, training and installation.

CONCLUSION

Based on the results of the three month test period, Teton-Nedco purchased the Aquamite V-H unit for the pilot restoration and decommissioning project. We feel that the EDR process has satisfactorily proven its amenability to HCO_3^- leach ISL water treatment requirements and this and a larger unit have been incorporated into the commercial scale flow sheet. Ease of operation, mechanical availability, capital and operating costs comparable to alternate systems, the units ability to provide >80% water recovery at >80% salt rejection, and the cooperation of the manufacturer were all factors in the decision to use EDR at the commercial level.

The anticipated uses of EDR under commercial operation include:

1) Provision of a source of low TDS process water for Na_2CO_3 makeup, slurry product washing and post elution resin rinsing. The unit feed would be the 0.5 to 2% field overrecovery fluid.

2) Commercial scale wellfield restoration would be accomplished using an Aquamite 20 1.26×10^{-2} m^3/sec. (200 gpm) unit.

3) Process bleed reduction may be attempted by reducing product radiometric levels to a point where the solution is usable for construction water, dust control, drilling, plant washing or, with appropriate approvals, surface discharge.

At this time, the Aquamite V-H unit continues to operate and a "state of the art" pilot scale wellfield restoration is nearing completion.

RANDOL INTERNATIONAL (1980) completed a multi-client report on continuous ion exchange (CIX) and resin in pulp (RIP) systems for uranium recovery. This report was over 2,000 pages long dealing with just that one aspect of ion exchange. Here there is room for a general summary of the principles and main features of CIX systems, their applicability, and to identify the main equipment suppliers, as well as sources of further information and expertise.

Ion exchange is routinely employed to demineralize feedwater for boilers in steam generation for metallurgical use (e.g., acid leach uranium mills use heat for leaching) and for steam-generated power stations. These boiler feedwater demineralizers generally use fixed-bed ion exchange systems employing cation as well as anion exchange resins either in mixed or separate beds. Fixed-bed IX systems operate in a downflow mode and need well-filtered feedwater with the lowest possible suspended solids. IX is generally cost effective compared with other desalination processes at low TDS levels, say 100 mg/l in feedwater, and where ultra high purity water is required.

Ion exchange is employed for desalination as mentioned above or for selective removal (and/or recovery) of one or more ions from a mixed solution. For example, IX has been employed for many years as the preferred way to recover uranium from leach solutions. Earlier vintage plants, e.g., Hartebeestfontein Gold Mining Company Ltd. on the west rim of the Witwatersrand, employs fixed-bed merrygoround ion exchange systems. In more recent times, however, continuous ion exchange recovery systems employing multi-stage upflow fluid-bed systems have been installed at uranium plants. The continuous ion-exchange systems handle larger flowrates in plants that are more compact than the older fixed-bed systems and, most importantly, they can tolerate small amounts of suspended solids in their feed. When the clarification equipment needed in conjunction with fixed-bed systems are taken into account, a well designed, constructed, and operated CIX plant is also more economical than fixed-bed systems. CIX systems have also been installed for uranium recovery from in situ leaching operations, notably in Texas.

For higher grade uranium solutions, the more selective SX process would generally be preferred except where there is concern for the effects of organic entrainment losses on the environment (e.g., Agnew Lake) or its effects on underground wellfield permeability.

For desalination of effluents, for example of acid mine drainage on the Witwatersrand where TDS level rise in Vaal Dam water has become a primary concern, CIX has been considered but apparently rejected in favor of other desalination processes such as R.O. and EDR because:

- At higher salt loads (1,500-2,000 mg/l), EDR and R.O. offers better economics than CIX.

- Ion exchange resin elution and regeneration requires chemical addition. Thus, there are more chemicals in concentrated form to dispose of from IX systems than from membrane processes.

CIX FOR DESALINATION OF MINE DRAINAGE AND TAILINGS EFFLUENTS

HENDRY (1983) makes a valiant case for ion exchange as a desalination tool due to its versatility as a separation, purification, and concentration process capable of shunting ions from one solution to another. He points out that CIX requires only chemical energy to accomplish this and utilizes this energy with efficiencies often close to 100%. He points out that ion exchange offers advantages where useful or saleable chemicals can be recovered in which cases, brine disposal costs would be avoided.

Nevertheless, the advantages described by HENDRY (1983) appear to apply only in special cases. Furthermore, the ion exchange systems advocated in his paper are relatively complicated, involving five separate ion exchange steps which are likely to require special operating skills considering the challenges that the mineral processing industry experiences running even two-step (adsorption and elution) uranium recovery operations. Flowsheets from HENDRY (1983), which employ the innovative NIMCIX ion exchange system are illustrated below for NH_4OH, H_2SO_4 recovery, and for acid mine drainage treatment with recovery of $CaSO_4$ and sodium chloride. Despite this innovative approach to ion exchange processes, which HENDRY (1983) has demonstrated on a large bench scale at the University of Cape Town with support from the Water Research Commission, the Commission and industry have apparently elected to back membrane processes for further mine-site desalination development and demonstration.

Some surprising features of the University of Cape Town work are:

1) HENDRY (1983) proposed the use of gypsum seeding inside a CIX resin fluid-bed contactor allowing 90% water recovery from solutions with 1,750 mg/l TDS. A $CaSO_4$

FIGURE 1 FIVE COLUMN SYSTEM WITH NH_4OH RECOVERY

FIGURE 2 FIVE COLUMN SYSTEM WITH H_2SO_4 RECOVERY

FIGURE 3 ACID MINE DRAINAGE TREATMENT WITH RECOVERY OF SOLID $CaSO_4$ AND SODIUM CHLORIDE.

slurry with 50% solids is removed from the process when the calcium form cation resin is regenerated with H_2SO_4. 92% water recovery from 800 mg/l TDS water has already been demonstrated. In this process, H_2SO_4 and $CaSO_4$ can be recovered using H_2SO_4 and $Ca(OH)_2$ as regenerants.

2) HENDRY (1983) proposed the use of CIX for desalination of high TDS acid mine drainage containing high sulfates as well as high Ca, Mg, Fe, Al, and Mn levels. Strong anion resin exchanges anions for hydroxyl raising the pH to over 12 and thus precipitating almost all of the cations except Na which remains as NaOH. Then, both anion and cation removal is attained with one equivalent of $Ca(OH)_2$ as regenerant costing only RC0.002 (U.S. $0.001) per equivalent, giving a chemical cost of only R0.24/m³ for a 7,000 mg/l water (R1.20/m³ for strong cation/weak anion).

This calculated chemical cost is identical to that incurred if the AMD is simply neutralized using lime. But, it provides a remarkable quality improvement as shown by the results of batch work on samples of AMD tested at the University of Cape Town.

TREATMENT OF AMD WITH STRONG ANION RESIN

	pH	Na	Ca	Mg	Fe	SO_4
Feed	2.8	186	368	488	305	3,425
Product	12.5	186	145	0	0	13

HENDRY (1983) emphasized the early stages of this work and that there are problems relating to resin fouling by "aging" effects of the precipitated metal hydroxides and, particularly, the problem of economically removing the residual NaOH from treated water, especially where Na is high as is usually the case in AMD.

3) In treating treated sewage effluents, the buildup of organic fouling on resin beads was experienced, but this, beyond a certain equilibrium point, did not interfere with ion adsorption by the resin.

Bruce A. Hendry
Bill Randall (Ext. 333)

KADLEC and HUBNER (1976) reported an improved technique for brackish water deionization by ion exchange. Their paper was not obtained.

SIROTHERM PROCESS

A second innovative ion exchange desalination process in the SIROTHERM process developed by the CSIRO in Australia and described by BOLTO (1975) and BOLTO, et al. (1982).

The SIROTHERM Process is innovative in that it employs thermal regeneration of the loaded resin, i.e., it overcomes the problem of adding salts to the system for elution of resins and thereby adding more salts for ultimate disposal. It also employs magnetic resin allowing improved kinetics of smaller beads recovered by magnetic filters.

Sadly, the SIROTHERM process appears more suited to NaCl removal than the kinds of salts (e.g., $SO_4^{=}$, Ca^{++}, metal ions Fe^{++}, Mn^{++}, Cu^{++}, etc.) commonly encountered in mine-mill environments.

The SIROTHERM process currently being installed in a commercial-scale municipal supply in a suburb of Perth is described in more detail in Chapter 36 on chloride removal.

APPLICATIONS OF ION EXCHANGE FOR CONTAMINANT REMOVAL

U.S. EPA (1981) reviewed the use of ion exchange processes for metal removal which would allow wastewater purification and recycling in the metal finishing industry. They also review IX as a means of "end-of-pipe" pollution control and for chemical recovery, again oriented towards the metal finishing industry.

U.S. EPA (1981) acknowledged that although ion exchange processes have been commercially available for many years, widespread interest in their use for metal finishing pollution control has developed only recently. They point out that one reason for the new wave of interest is the broad range of resins available today. They felt that since hydroxide precipitates of metals are "hazardous" wastes, the concentrates produced in IX systems would be more amenable to metal recovery than are hydroxide precipitates. In this latter conclusion, the EPA may be misguided since the small-scale recovery of metals from solutions or precipitates is unlikely to be more than a pipe dream for years to come due to the depressed state of most metal markets and the poor economy of small-scale metal recovery and purification processes. Nevertheless, the EPA has forced the metal finishing industries to treat and dispose of effluents and concentrates and is working hard on the mining and mineral processing industries as well. In some cases, metal chemicals may be recovered in useful form at an improved economy compared with costly disposal procedures.

The U.S. EPA (1980) summary report is available from:

U.S. ENVIRONMENTAL PROTECTION AGENCY
Industrial Environmental Research Lab
Cincinnati, OH 45268

This report includes the following items of general interest:

Table 1 - Selectivity of Ion Exchange Resins in Order of Decreasing Preference

Strong Acid Cation Exchanger	Strong Base Anion Exchanger
Barium	Iodide
Lead	Nitrate
Calcium	Bisulfite
Nickel	Chloride

Mn^{2+}	1.2
Ca^{2+}	1

* Selectivity Coefficient for the metal Over Calcium Ions at pH 4

Table 3 - Cost of Commercially Available Resins (1980)

Resin	Cost ($/ft²)
Strong Acid Cation	$ 50-100
Weak Acid Cation	100-150
Strong Bace Anion	150-200
Weak Base Anion	150-200
Chelating Resins	200-250

Table 6 - Chemical Prices (1980)

Reagent	Description	Cost $/Lb.
HCl	Carboys 32% HCl	$0.05
NaOH	Carboys 50% NaOH	$0.075
Hydrated Lime	100 lb. Bags	$0.05
$NaHSO_3$	100 lb. Bags	$0.20
H_2SO_4	Carboys 97% H_2SO_4	$0.05

The examples cited by U.S. EPA (1981) have little or no applicability to mining and mineral processing waste streams. Nonetheless, the need to recycle water and solutions and to treat effluents prior to discharge does affect the mining and mineral processing industry, and ion exchange processes have, in a few cases, been applied usefully.

SLATER, et al. (1978) tested the use of continuous ion exchange for the removal of environmental contaminants from waste streams typical of the mining industry.

A fluidized bed, continuous ion exchange unit was used to treat a synthetic minewater containing 56 mg/l Cu, 3.5 mg/l Ni, 0.3 mg/l Co, 1.0 mg/l Fe, and 20.0 mg/l Ca at pH 4. Strong acid resin, Amberlite 200C was used in the sodium form. After five-minute upflow intervals, the loaded resin was transferred by eluate to the top of an elution column for elution by NaCl. A continuous system was devised. It is not known what the results of these tests were or whether they indicated a cost effective treatment process. The report and further information would be available from:

CANMET
Energy Mines and Resources Canada
555 Booth Street
Ottawa, Ontario K1A 0G1
(613) 995-4194
Gordon M. Ritcey
M. J. Lucas

As a result of these tests, no CIX effluent treatment plants have been installed in Canada or elsewhere, although some would like to see further development work in this area.

DIFFERENCE IN PERFORMANCE - FIXED VS. FLUID-BED IX

This report does not have room to accommodate a description or discussion of the various ion exchange process principles or the pros and cons of each. However, one important difference is mentioned between fluid-bed multiple-stage systems and plug flow (downflow fixed-bed) systems. In a counter-current process, the number of stages is a critical factor in the efficiency of the process as is demonstrated by the wellknown McCabe-Thiele diagram. In a plug flow system, as long as solutions are well disributed and channelling avoided, the column acts as an unlimited number of stages. In fluid-bed, multi-stage systems, each stage is assumed to be perfectly mixed, and the system is limited to the number of tanks installed, each acting as a stage. In this sense, the fixed-bed plug flow system should theoretically allow higher loadings of metal ions on the leading edge and the lowest possible levels of ions in the effluent solutions. It is important to distinguish between continuous plug flow systems and two or three-stage merry-go-round fixed-bed systems which effectively present only two stages of adsorption. As mentioned above, continuous plug flow and fixed-bed systems are less tolerant to physical fouling of the IX bed by particulates filtered from the feed solution.

APPLICATIONS OF CIX FOR CONTAMINANT REMOVAL

Ion exchange systems are also employed for the selective removal of undesirable contaminants, e.g., uranium or molybdenum, from process streams. Two examples where effluents are treated by ion exchange prior to discharge primarily to meet discharge premit requirements are the Cotter Corporations's Schwarzwalder minewater at Golden,

THREE COLUMN IX SET FOR URANIUM EXTRACTION
Shown for sake of comparison

Colorado, and Climax Molybdenum Division's tailings effluent treatment plant at Climax, Colorado. These two water treatment plants were installed primarily to remove uranium and molybdenum respectively. The Cotter installation is described in Appendix I trip reports, and also by PALMER, et al. (1984) while GOTT and LAFERTY's (1977) description of the CLIMAX unit is inserted below.

A third large-scale effluent treatment plant employing ion exchange for selective removal of uranium is the Wyoming Minerals Corp. plant that treats Bingham Canyon acid copper mine drainage in Utah. This operation employed Chem-Seps' "Higgins Loops" to treat 1,500 m^3/h (6,600 U.S. gpm) solution containing 6-7 mg/l U_3O_8. This plant was described by RANDOL (1980), and the trip report from that investigation is also inserted below. This trip report is critical of Chem-Seps in that several problems were experienced in this and other plants. It is fair to state, however, that the "Higgins Loop" is a very innovative system, and that if it were to be installed to achieve half a quantum leap forward in terms of specific flow rates rather than the whole quantum leap attempted, this system would undoubtably give rise to fewer mechanical problems.

Several other ion exchange applications for specific removal of contaminants have been installed by Chem-Seps such as nitrates from municipal water supplies and, although these do not refer to mine-mill applications, they are analogous and can be taken into account to demonstrate the practical use of CIX for a wider range of contaminant removal. For example, FICKLIN (1983) reported on the separation of arsenic (III) and arsenic (V) in groundwaters by ion exchange using Dowex strong ion exchange resin. The Dowex IX8 resin 100-200# in acetate form was shown suitable for arsenic removal. More information can be obtained from:

W. H. FICKLIN
U.S. Geological Survey
Box 25046
Denver, CO 80225
(303) 888-3001

WILMOTH, et al. (1979) tested lime neutralization, reverse osmosis, and ion exchange for the removal of arsenic, Cd, Cu, Hg, Ni, Se, Zn, B, and P from mine drainage. All but B and P were removed. They found that although R.O. and ion exchange were slightly more effective overall than neutralization, the chemical requirements and need for subsequent waste treatment offset their advantages.

SYNEX RESINS

Ion exchange can be used for selective recovery or removal of base and heavy metals. Most of the wellknown ion exchange resin suppliers listed below offer a range of metal selective resins for this purpose. Of course, the economics of these processes is

adversely affected by the currently depressed metal markets, but there may be other incentives such as the need to remove contaminants prior to discharge of effluents.

One example of selective IX recovery of ions, e.g., Cu in the presence of Fe from acid solutions (pH2), is available from:

A mixture of 10% active SYNEX DN or DD and SYNEX XB-1 is employed which is eluted with 10-15% H_2SO_4 to recover copper in an eluate suitable for electrowinning.

COTTER CORPORATION - SCHWARZWALDER MINE

The most outstanding application of CIX for minewater treatment encountered so far from a performance point of view is the minewater treatment plant at the Schwarzwalder Mine, Golden, Colorado. Performance of this 500 U.S. gpm plant is described in greater detail in Appendix I. Uranium is reduced from 3-3.5 mg/l U_3O_8 in feedwater to 10-20 ppb U_3O_3 in the product water. In addition, elements such as Cd and copper are reduced to levels of 0.0004 mg/l Cd and 0.005 mg/l Cu and radium from 50-100 p Ci/l to 5 p Ci/l which is remarkably good performance and a breakthrough in effluent treatment technology.

Information on this plant, its design, an its operation can also be requested from:

The CIX system employed uses two downflow IX beds in series and a downflow resin elution system. One of the tricks in achieving this exceptional adsorption performance is a step inserted to treat loaded resin between adsorption and elution to react any carbonates (uranium is adsorbed as a carbonate complex in this case). Were it not for this step, CO_2 generated by reaction between carbonates and the acid eluant would cause

channelling in the column which would result in less efficient elution and consequently a less effluent adsorption performance as well.

ION EXCHANGE SYSTEMS

FIXED-BED SYSTEMS - WATER CONDITIONING

Conventional ion exchange systems used in water demineralization prior to use as boiler feed or as a water conditioning step in municipal supply can be obtained from virtually any water treatment equipment supplier. Technology used in this area does not seem to have changed much since the attached description on water conditioning was written in 1970.

There is along list of suppliers of these systems including:

Ultra high purity water is produced using several technologies including the TRIOBED process described by WOLFF and ABRAMS (1979) of the Diamond Shamrock Corporation, Redwood City.

FUNDAMENTALS OF ION EXCHANGE IN WATER TREATMENT

by C. S. Parks and I. M. Abrams, Diamond Shamrock Chemical Company

Brief History

The exchange of ions is a phenomenon universally spread throughout nature. Its utilization by man (for the purification of brackish water) has been given some credibility in the Old Testament, Book of Exodus (Chapter 15, verses 23-25). About 1850, two English agricultural chemists, Harris S. Thompson and John T. Way observed a stoichiometric exchange between ammonium and calcium in soils. In 1876, Lemberg identified crystalline aluminosilicates as the exchangers and showed that the exchange of the cations was stoichiometrically reversible. Various natural minerals, called zeolites were found to have exchange characteristics suitable for the softening of water, which involves the exchange of calcium and magnesium for sodium. In 1904 a German chemist by the name of Gans produced the first artificial aluminosilicates. These artificial zeolites had effective capacities two to three times those of the naturally occurring minerals. Synthesis of these zeolites stimulated the industrial development of water softening.

These inorganic zeolites, though suitable for water softening reactions, are not capable of resisting acids, and therefore cannot be used in the exchange of hydrogen ions. The first acid-proof cation exchange materials were produced between 1923 and 1927 by the sulfonation of coal. Two English chemists, Adams and Holmes, successfully synthesized the first organic ion-exchange resins in 1936, thereby opening the way for complete deionization of water.

Definitions

Ion-exchange resins are by definition insoluble solids containing fixed cations or anions capable of reversible exchange with mobile ions of the opposite sign in the solutions with which they are brought into contact.

When salts are dissolved in water, the various ions which make up these salts dissociate and are free to enter into chemical reactions with other ions. In solution, the salt gives positively charged cations and negatively charged anions. The exchange of desirable cations and anions for undesirable ones by an ion-exchange resin forms the basis for the use of ion exchange as a unit operation in water treatment.

Most ion-exchange resins are made by first forming an insoluble, infusible polymer, then adding active acidic or basic groups by appropriate chemical reactions. The polymer matrix must be physically and chemically resistant to the many conditions imposed upon it both during the production of the ion-exchange resin and in the subsequent use of the product. The majority of commercial ion-exchange resins are based on copolymers of styrene and divinyl-benzene, prepared in bead form. A number of ion-exchange resins are also based on phenol-formaldehyde and epoxy-polyamine condensates. The phenolic-based resins are granular rather than spherical and the epoxy resins can be produced in either bead or granular form.

Special Terms for Ion Exchange in Water Treatment

Two different systems are employed in the U.S. to express the performance of ion-exchange resins. The chemists talk in terms of milliequivalents per milliliter or milliequivalents per dry gram to describe exchange capacity, and equivalents or grams per liter to express concentration of insolution ions. The water treatment engineer speaks in terms of kilograins per cubic foot, grains per gallon and parts per million. To further complicate matters, the chemist works with chemical equivalents whereas the engineer usually converts everything to calcium carbonate equivalents.

In order to work with ion exchange in water treatment, one should become familiar with the system of expressing concentrations and capacities as calcium carbonate equivalents. Ion-exchange resin performance and data (for applications in water treatment) are nearly always presented as calcium carbonate equivalents, particularly in U.S. literature. The use of this system is based upon the existence of

Presented at the 7th Annual Liberty Bell Corrosion Conference

both calcium and carbonate ions in water and the fortuitous circumstance that the molecular weight of the compound is 100. Also, one of the major objects of ion exchange in water treatment is to prevent the deposition of calcium carbonate from water.

Water Analysis for Ion Exchange Calculations

A reasonably accurate water analysis is required to design an ion exchange installation for water treatment. With most natural waters, the analysis can be presented in a form similar to that in Table I.

TABLE I
WATER ANALYSIS FORM

CATIONS		ANIONS	
Alkaline Earth Cations or Total Hardness	Ca^{++} Mg^{++}	Total Alkalinity ALK	OH^- CO_3^{--} HCO_3^-
Alkaline Metal Cations	Na^+ K^+	Total Salts of Strong Acids or TMA	SO_4^{--} Cl^- NO_3^-
Total Dissolved Solids TDS	=	Total Dissolved Solids TDS	=
		CO_2 SiO_2 pH	

It is common practice to state the amount of dissolved impurities as the cations and anions actually determined by analysis. These amounts may be expressed in terms of the ions themselves or as their calcium carbonate equivalents. For ion exchange work it is highly convenient to have all values expressed as calcium carbonate equivalents. Table II lists the factors which are used to convert concentrations as the various ions to concentrations as calcium carbonate ($CaCO_3$). To convert any ion concentration to its $CaCO_3$ equivalent, simply divide 50 (the equivalent weight of calcium carbonate) by the equivalent weight of the ion in question, then multiply the quotient by the part per million concentration as the ion. When a water analysis has been converted to calcium carbonate equivalents, the sum of the total cations must equal the sum of the total anions. This is a convenient way to check the values given in a water analysis.

Water Softening With Cation-Exchange Resins

In a great many industrial, municipal and commercial applications, it is desirable to remove or reduce the hardness of water before it is used. Boiler feedwater, commercial laundries, many industrial processes, and to some extent, cooling water, all require soft water.

The hardness in water is composed of the alkaline-earth cations, calcium and magnesium. The sum of these two is the total hardness. The total hardness is then broken down into two categories, the carbonate or temporary hardness and the non-carbonate or permanent hardness. Temporary hardness is the most common and is responsible for the deposition of calcium carbonate scale in pipes and equipment. The following equation illustrates how this scale is formed:

$$Ca(HCO_3)_2 + \text{Heat} \rightarrow CaCO_3 + H_2O + CO_2$$

Non-carbonate hardness will react with the carbonate alkalinity frequently found in soap and detergent formulations to form insoluble deposits. The following equation illustrates this reaction:

$$CaSO_4 + Na_2CO_3 \rightarrow CaCO_3 + Na_2SO_4$$

Soaps react with hardness in water to form insoluble and unsightly scums, particularly the familiar "bathtub ring".

The softening of water by ion exchange is relatively simple, but highly effective. The process consists of passing hard water through a column of cation-exchange resin in the sodium form. The sodium on the resin replaces the objectionable calcium and magnesium ions. Figure 1 illustrates the regeneration and service cycles of a water softener and shows the various ion exchange operations which take place.

The amount of hardness removed by one cubic foot of cation-exchange resin is directly dependent on the amount of regenerant salt used to convert the resin to the sodium form. Table III illustrates the capacities for

various regenerant levels of Duolite C-20, a common cation-exchange resin used in water softening.

In order to determine the volume of water which can be softened by one cubic foot of cation-exchange resin, it is first necessary to select the desired regeneration level and its corresponding capacity in kilograins per cubic foot. By way of illustration, let us assume a water which contains 171 parts per million total hardness (as calcium carbonate). Question: How many gallons of this water can be softened per cubic foot of resin? From Table III we see that a capacity of approximately 24 kilograins/cubic foot can be obtained by regeneration with 8 pounds of NaCl per cubic foot. To obtain capacity, we must first convert ppm (as $CaCO_3$) to grains per gallon, as $CaCO_3$. Since 17.1 ppm equals 1 grain per gallon, the water in question contains $\frac{171}{17.1}$ or 10 grains per gallon total hardness, as $CaCO_3$. At the selected regeneration and capacity level (8 lbs. NaCl and 24 kilograins, respectively), each cubic foot of resin will soften $\frac{24,000}{10}$ or 2,400 gallons of water before it requires regeneration.

Ordinary waters containing up to 1500 ppm total dissolved solids are readily softened by conventional techniques, as described above. However, with waters containing between 1500 and 5000 ppm total dissolved solids, somewhat unconventional arrangements of equipment and techniques of regeneration are required. In order to effectively soften waters which contain more than 5000 ppm, it is necessary to employ a weak-acid cation resin in the sodium form. The technique, involving a two-step regeneration, has been called the "CARBO-SOFT" process.

Dealkalization of Water by Ion Exchange

Alkalinity in water can be present as bicarbonate, carbonate, or hydroxide. Bicarbonate alkalinity is by far the most common. When water with carbonate or bicarbonate alkalinity is heated, the alkalinity is broken down to carbon dioxide, as shown by the following reactions.

$$2\ HCO_3^- + \text{Heat} \rightarrow CO_3^= + CO_2 + H_2O$$

$$CO_3^= + H_2O + \text{Heat} \rightarrow CO_2 + 2\ OH^-$$

$$\leftarrow CO_2 + H_2O = = H_2CO_3 \rightarrow$$

As indicated by the last reaction, carbon dioxide combines with the water to give carbonic acid which can cause corrosion of iron or steel equipment. The corrosion products react further with alkalinity and the deposits can build up in the same manner as calcium carbonate scale.

Alkalinity in raw water can be reduced by several ion-exchange processes. The simplest and most straightforward process is chloride-cycle anion exchange. This process is usually preceded by a water softener. A schematic representation of a chloride-cycle dealkalizer — with the reactions that take place — is illustrated in Figure 2. The resin used in this application is usually a Type 2 strong-base anion exchanger, such as Duolite A-102D.

The use of weakly-acidic cation exchange resin for the dealkalinization of water is becoming increasingly popular with the advent of the new high capacity weak-acid resins (such as Duolite CC-3). These resins simultaneously remove both hardness and alkalinity from waters where the ratio of the total hardness to alkalinity is less than or equal to one. When the total hardness to alkalinity ratio is greater than one, hardness is effectively removed, but "leakage" of hardness is observed. The operation and regeneration of a weak-acid dealkalization unit and degasifier are illustrated in Figure 3.

If the total hardness to alkalinity

FIGURE 1. WATER SOFTENING

ratio is greater than one, there are two arrangements which make it possible to achieve complete removal of both hardness and alkalinity. The first arrangement is illustrated in Figure 4 and is often referred to as a "split-stream" system. In this arrangement, the influent water is divided into two parallel flows. One portion is passed through a sodium-cycle water softener and the other portion is passed through a hydrogen-cycle cation-exchange unit. These two flows are then blended and passed through aerator or decarbonator. The sodium-cycle water softener removes the hardness from the water but allows the alkalinity to be carried forward. The hydrogen-cycle cation unit removes the hardness from the water and also creates some free mineral acidity. When these two flows are blended, the free mineral acidity from the hydrogen-cycle cation unit reacts with the alkalinity from the water softener to produce carbon dioxide and water. The CO_2 can be eliminated by aeration or degasification. The exact amount of alkalinity present in the finished blend from this type of system can be very closely controlled by varying the ratio of flows between the two units.

The second means of producing soft, dealkalized water when the hardness to alkalinity exceeds one involves the use of a layered-bed cation unit. This system consists of a single tank ion-exchange unit with a layer of lower density weak-acid resin on a layer of higher density strong-acid resin. The weak-acid resin is regenerated with a mineral acid and the strong-acid resin with sodium chloride. The temporary or carbonate hardness is removed by the weak-acid resin and the non-carbonate or permanent hardness is removed by the strong-acid resin. The effluent from this duo-bed unit is then passed through an aerator or decarbonator for removal of CO_2. The reactions of the individual resins are illustrated in Figure 3 for the weak-acid resin and Figure 1 for the strong-acid resin.

Demineralization with Ion Exchange

Many industries such as manufacturers of electronic components and the public utilities, in their quest for better products and higher output capacities, have found that increasingly larger quantities of extremely high purity water are required for effective operation. Distillation cannot achieve the quantity and quality of water required by such applications. The relative ease and low cost of providing a high purity water by ion exchange has led to widespread use of the process.

The design and selection of the proper ion-exchange system and the correct type of ion-exchange resins to fulfill the requirements of a particular application is the job of a qualified equipment manufacturer or de-

FIGURE 4. DEALKALIZATION BY "SPLIT STREAM"

FIGURE 5. DEALKALIZATION BY LAYERED-BED CATION

FIGURE 6. HYDROGEN-CYCLE CATION EXCHANGE

sign engineer. By careful choice of the various ion-exchange resins, it is possible to design many different types of systems to accomplish the same end. Some systems may have high initial capital cost, but low operating expense. Other systems have low capital cost, but higher operating costs. Also the selection of resins and arrangement of equipment will have a direct bearing on the quality of the final effluent from the demineralization system.

Demineralization of water by ion exchange is achieved by passing the water through cation and anion-exchange resins. The cation exchanger in the hydrogen form exchanges hydrogen ions for the positively charged cations in the water. The anion-exchange resin in the hydroxide form exchanges hydroxide ions for the anions in the water. The net result of this operation is replacement of the dissolved salts with water.

These operations can be conducted with the cation and anion exchangers in separate vessels or in a single vessel. Figure 6 illustrates the reactions which occur when a water passes through a column of a strong-acid cation-exchange resin in the hydrogen form. The effluent from such a unit is then carried forward to an anion-exchange resin. This might be either a weak-base or a strong-base resin. A weak-base resin adsorbs the entire acid molecule; that is, if hydrochloric acid (HCl) is put through a weak-base resin, the entire HCl molecule is taken up by the resin, not just the chloride ion. This is illustrated (in reverse) by the equation in Figure 7 which shows the regeneration of a weak-base anion resin. The process consists of a typical acid-base reaction which forms the salt of that acid in water. Since this reaction goes to completion, it is possible to regenerate a weak-base resin with near-stoichiometric amounts of regenerant. In many applications, the weak-base resin is followed by a strong-base anion resin. The spent regenerant from the strong-base anion unit is sufficient to regenerant the weak-base anion resin in most cases.

Figure 8 illustrates a typical strong-base anion unit operating in the hydroxide cycle. The mineral acids, carbon dioxide, and silica, which have been created by the cation exchanger, are removed by contact with the strong-base resin in the hydroxide

form. The final product from this unit is demineralized water. With three-bed systems, the strong-base unit removes only the CO_2 and SiO_2 which pass through the weak-base unit.

As mentioned before, it is possible to use many combinations of the various cation and anion-exchange resins to demineralize water. Figure 9 shows some of the various possible combinations and arrangements of ion-exchange resins. It also indicates the conductivity, pH and anticipated silica which might be expected from the various layouts. This illustration alone should further dramatize the need to consult water treatment equipment manufacturers or design engineers when selecting the proper ion-exchange system and resins to do a specific job.

IWC-79-33
Progress Report

OPERATING EXPERIENCE WITH TRIOBED IN THE PRODUCTION OF ULTRA HIGH PURITY WATER

J.J. Wolff, Dia Prosim, Vitry-sur-Seine, France

and

I.M. Abrams, Diamond Shamrock Corp., Redwood City, Calif.

With respect to requirements for ion exchange condensate polishing, the definition of "ultra high purity water" has been changing rapidly during the past decade. Whereas 5 ppb leakage was acceptable in the sixties, 1 ppb became the target in the mid seventies. As we approach the eighties, the target is heading toward 0.1 ppb. This would indeed be a remarkable achievement in a relatively short period of time. Cooperative efforts by resin manufacturers, equipment vendors, and utility operators are promising to reach this target. One such effort involves the development of TRIOBED. This improvement in mixed bed operation and its performance at three power stations in Europe is the principal message of this report.

THE ION LEAKAGE PROBLEM

As pointed out in a 1976 presentation at this conference (1), resins which are completely regenerated to the H/OH forms or to the NH_4/OH forms do not leak ions. By calculations using mass action equilibrium equations, it was shown that sub-ppb leakages could be readily achieved in H/OH operation, but that very high degrees of regeneration and extreme diligence had to be practiced to achieve such very low ion leakage with NH_4/OH operation. For operation beyond the ammonia break, residual sodium in the cation exchanger would have to be less than 0.5%. For chloride leakages below 1.5 ppb, the anion exchanger should contain less than 10.8% residual chloride at pH 8.8 and less than 2% chloride at pH 9.6.

One means of reducing the chloride content of the strong-base resin is to use a two-step regeneration (2). Polyvalent anions readily replace chloride, then hydroxide readily replaces the polyvalent anions. Figure 1 illustrates conversion to the hydroxide form of a Type 1 strong-base anion exchanger (Duolite A-161) from both the chloride and sulfate forms. In the event of a condenser leak, leading to a partial exhaustion of the anion resin with chloride, subsequent leakage of this chloride from the resin could be minimized (especially in NH_4/OH operation) and caustic consumption reduced by a two-step regeneration, for example, with dilute sulfuric acid followed by caustic soda.

It has long been recognized that the principal difficulty in achieving sub-ppb leakage and ultimate quality effluents in mixed bed operations is due to the cross-contamination of resins during

hydraulic separation prior to regeneration. If not completely separated, a minor portion of the cation exchanger contaminates the anion exchanger and is converted to the sodium form on regeneration with caustic soda. Similarly, a portion of the stray anion exchanger is converted to the bisulfate form when contacted with the sulfuric acid regenerant. Thus, incomplete separation subsequently leads to escape of sodium and sulfate ions from the mixed beds.

The problem is particularly aggravated with external regeneration, which is almost universally used by utilities in the U.S. for condensate treatment. The practice of external regeneration and NH_4/OH operation has been a severe challenge to the industry in the attempt to reach the target of sub-ppb leakage.

This challenge has been met in part by some ingenious methods which attempt to remedy the cross-contamination problem in mixed bed operations. These patented methods, such as Ammonex (3), Calex (4, 5) and Seprex (6) have been described adequately in earlier reports and need not be further explained here.

These methods are designed primarily to reduce sodium leakage. Until quite recently the potential for leakage of sulfate was neglected. However, this potential was pointed out by one of us in 1976 (1) and confirmed in England on H/OH condendate polishers (7, 8). The initial sulfate leakage from a freshly regenerated mixed bed in the H/OH cycle is illustrated in Figure 2. This is due to the presence of anion exchanger in the cation resin when the latter is regenerated with sulfuric acid.

THE TRIOBED PROCESS

The process was developed by Dia Prosim in France. The first industrial scale system was installed in Belgium in 1976. About thirty Duolite TRIOBEDS are currently in operation and about thirty more scheduled for startup on the near future. Operating results are now becoming available.

TRIOBED is designed to prevent rather than cure the problem due to cross-contamination in mixed beds. The principle, illustrated in Figure 3, is quite simple. The resin mixture consists of three components: a strong-acid cation exchanger, a strong-base anion exchanger, and an inert resin. The specific gravity and particle size of the three components are designed to separate virtually completely into three distinct layers after ten minutes of backwash and settling. In practice, the layer of inert resin is 10 to 20 cm (4 to 8 inches) in depth.

Either internal or external regeneration can be used. With the former, the inert layer provides a buffer zone to prevent contact between acid and the anion exchanger or between caustic and the cation exchanger. In external regeneration, the inert resin layer serves to prevent carryover of the cation exchanger with the anion exchanger.

TRIOBED Resins

The Duolite TRIOBED ion-exchange resins (Duolite C-26TR and A-161TR), have been optimized to give maximum regeneration efficiency and high resistance to osmotic shock. Experience to date has demonstrated that these resins are capable of achieving sub-ppb leakage for at least three years with little or no deterioration in performance.

Studies were carried out to optimize the particle sizes and densities of the three resins, factors which are necessarily interrelated. Figure 4 shows a plot of the settling rate versus particle diameter of the cation exchanger, the anion exchanger and the inert polymer used in the Duolite TRIOBED process. These studies demonstrated that Duolite C-26TR, with a minimum diameter of 0.7 mm (maximum settling rate of 95 m/h) will separate completely from Duolite A-161TR, which has a maximum diameter of 0.85 mm (maximum settling rate less than 55 m/h). The inert resin (Duolite S-3TR) has a specific gravity intermediate between those of the cation and anion exchangers; its particle size is designed to allow separation from both during backwash and settling. In terms of U.S. Standard Sieves, the Duolite C-26TR is essentially larger than 25 mesh, the Duolite A-161TR smaller than 20 mesh, and the Duolite S-3TR between 22 and 25 mesh.

CASE HISTORIES

1. Kerncentrale EBES, Doel, Belgium

Full-scale testing of the Duolite TRIOBED has been conducted at the Doel Nuclear Power Station near Antwerp, Belgium. Doel 1 and 2 are Westinghouse PWR designs, each with a net electrical output of 392 MW. During construction, the decision was made to control steam generator chemistry with "all volatile treatment" (AVT). As a result, full flow condensate polishers were retrofitted into the systems to cope with anticipated condenser leaks. The original polishers, built by Degremont Sobelco, consisted of precoat (cellulosic) filters to remove "crud", cation exchangers to remove ammonia, and deep mixed beds to remove dissolved salts. (The design is shown schematically in Figure 5.) Because of space limitations, the resin beds were regenerated in the service vessel.

As a result of numerous problems encountered with the initial condensate polisher system (9), the precoat filter was eliminated and the Duolite TRIOBED installed at Doel 1 in January, 1976 and at Doel 2 one year later.

In the original installation, the first cation exchanger vessel contained 14.5 m^3 (512 ft^3) of Duolite C-26C and was operated at a flow rate of 90 m/h (37 gpm/ft^2). The mixed bed, with a diameter of 3.2 m (10.5 ft), contained 5.6 m^3 (198 ft^3) of Duolite C-26C and 7.5 m^3 (265 ft^3) of Duolite A-161TR. It was operated at 110 m/h (45 gpm/ft^2). On conversion to TRIOBED, the Duolite C-26C was replaced by Duolite C-26TR, having a particle size better suited to efficient separation. However, the Duolite A-161C was retained because it was still in good operating condition and had a particle size suitable for TRIOBED. Duolite S-3TR was added to each mixed bed to give the following volumes:

Duolite A-161C:	6.6 m^3	(233 ft^3)
Duolite S-3TR:	1.6 m^3	(56 ft^3)
Duolite C-26TR:	4.8 m^3	(170 ft^3)

The flow rate is 1000 m^3/h (4000 gpm) per TRIOBED. The linear velocity is 108 m/h or 44 gpm/ft^2. The cation exchanger is regenerated with 5% sulfuric acid at a dosage of 1233 kg (16 lbs/ft^3), the anion exchanger with 3.5% caustic soda at a dosage of 900 kg (8.5 lbs/ft^3). The resins are regenerated simultaneously, the caustic soda downflow and the acid upflow, the effluents meeting at the intermediate collector.

Prior to the installation of TRIOBED at Doel 1, the mixed bed actually contributed an estimated 0.45 ppb of sodium to the condensate. From the studies made, it was estimated that sodium

concentration in the steam generator was an average of 23 ppb when the mixed bed polisher was in operation compared to only 12 ppb when not in operation.

A comprehensive study of the TRIOBED operation was made by a team from the CEGB using a mobile unit equipped with very sophisticated analytical instrumentation capable of measuring extremely low sodium and sulfate levels. This study was conducted during the summer of 1977. The results show that the sodium level at Doel 1 falls below 1 ppb even at the beginning of a cycle and goes below 0.1 ppb during much of the working cycle. Similarly, the sulfate leakage falls to about 1 ppb after only a few hours, a result which is all the more remarkable in that the anion exchangers had been in service for 33 months at Doel 1 and 25 months at Doel 2 at the time of monitoring.

Average results

Sodium: At Doel 1, the mean sodium level in the treated condensate during the test period was 0.08 ppb for one of the TRIOBEDS and 0.10 ppb for the other. At Doel 2, the effluent sodium levels of both TRIOBEDS was about 0.25 ppb. The somewhat higher leakage at Doel 2 was probably due to the less centralized position of the intermediate collector in the inert layer.

Chloride: Analyses for chloride in the steam generator indicated levels in the TRIOBED effluents of 0.1 to 0.2 ppb.

Sulfate: Measurements of effluent sulfate did not always check with levels found in the steam generator. However, it can be said that mean values did not exceed 1 ppb and probably fell below this value most of the time.

In general, the tests on the TRIOBED installation at Doel suggested that the leakages (in H/OH operation) were 1/2 to 1/5

of those found with the more convential mixed beds.

2. Interescaut Thermal Power Station, Schelle, Belgium

Early in 1979, the conventional resins in the mixed-bed polisher at Schelle were replaced by TRIOBED resins. The vessel was 2.31 meters (7.6 feet) in diameter and was charged as follows:

Duolite	Volume		Bed Depth	
	Liters	cu.ft.	cm	inches
C-26TR	2,400	85	57	22.4
A-161TR	2,600	92	62	24.4
S-3TR	800	28	19	7.5

The intermediate distributor is centered in the layer of inert resin so that it is equidistant from the cation and anion interfaces after separation.

The condensate is first filtered through AMA cartridge filters (10 mμ) and then through the resin colums at a rate of 305 metric tons per hour, equivalent to a flow of about 75 m/h (30.6 gpm/ft^2). The condensate is treated with 1 ppm NH_3 to give a pH of 9.4.

The resins are regenerated in the working vessel (internally). After separation into three distinct layers by 15 minutes of backwash at 12 m/h (4.9 gpm/ft^2), the resins are regenerated simultaneously, the cation upflow and the anion downflow. The spent regenerants are discharged through the collector buried in the inert resin. The cation exchanger is regenerated with HCl at a dosage of 150 g/l (9.36 lbs/cu.ft.) at a concentration of 10%; the anion exchanger with NaOH, 150 g/l at 4%.

As shown in Figure 6, sodium quickly falls below 1 ppb and levels out at 0.3 ppb. With the cation exchanger in the ammonium form at the end of the cycle and the effluent ammonia at 15 ppb,

the sodium reaches only 1.5 ppb.

Chloride determinations indicated leakage values below 1 ppb at influent levels of 3 to 8 ppb. This is particularly impressive since the cation exchanger was regenerated with HCl.

3. Fawley Power Station (CEGB, UK)

Fawley is a fossil fuel plant. The condensate treatment system, which has been in service since 1974 with standard macroporous resins, was of the same design as those already in use in several British nuclear power stations of the AGR type. The condensate polisher was built by Kennicott Water Treatment Co.

Fawley has four 500 MW units, each equipped with two mixed beds each treating 50% of the condensate. The vessels are 2.286 m (7.5 ft) in diameter and each contained 2.83 m^3 (100 ft^3) of cation exchanger and 2.12 m^3 (75 ft^3) of anion exchanger.

The condensate polishing rate is held constant (by recycle) at 540 metric tons per hour at a flow velocity of 133 m/h (54.3 gpm/ft^2). The condensate was usually treated with 0.2 ppm ammonia and the run stopped at or before the ammonia break (about 10 days). If condenser leakage occurred, a double regeneration was applied.

The resins are externally regenerated in a system which would be considered conventional in the U.S. The resins are transferred hydraulically from the service vessels to the regenerating unit through a 400 meter (1,312 ft) pipe containing several bends.

The cation regeneration/separation tank is 1.83 m (6 ft) in diameter and its collector was at a height which left 10 cm of anion exchanger with the cation exchanger. In other words, it

was designed to transfer most the anion exchanger, but to leave a portion in the cation regeneration vessel.

The resins were separated by backwash at 12 m/h (4.9 gpm/ft^2) and regenerated with 128 g/l (8 lbs/ft^3) of H_2SO_4 at 5% and 96 g/l (6 lbs/ft^3) of NaOH at 6%. The resins are rinsed separately to a conductivity of 50 micromhos/cm and then in the mix/storage vessel to 0.1 micromhos/cm.

The initial resins, used from 1974 to 1979, produced the following ion leakages after five years of service.

Sodium	-	0.2 to 1.0 ppb
Chloride	-	1 to 2 ppb
Sulfate	-	1 to 2 ppb.

It should be pointed out that conditions were quite favorable for low leakage – with H/OH cycles and relatively low ammonia concentration.

With the objective of obtaining experience with the three-resin system, the standard resins were replaced with Duolite TRIOBED resins in March, 1979. The existing system was not otherwise modified. Each of the six mixed beds was charged with 3 m^3 (106 ft^3) of Duolite C-26TR, 2.1 m^3 (74 ft^3) of Duolite A-161TR, and 0.5 m^3 (17.6 ft^3) of Duolite S-37R. The collector was placed to have 72 mm (2.8 in.) of inert resin above it and 106 mm (4.2 in.) below it.

A comprehensive monitoring program was scheduled and the Scientific Services Department of the South Western Region of the CEGB at Bristol has undertaken the difficult task of determining leakage values in the treated condensate. The program provides for investigation of both the H/OH and NH_4/OH cycles.

a. <u>H/OH cycle</u>

The existing conditions in service and regeneration were not changed.

Following backwash, separation of cation and anion resins is virtually complete. It is estimated that the amount of cation exchanger in the anion layer is less than 0.5%. After resin transfer, however, several centimeters of anion exchanger remains in the cation regeneration tank. This is most likely due to turbulence during transfer which results in the migration of a small portion of the anion exchanger to the cation layer. This portion is not transferred to the anion regeneration tank.

Until now, the incomplete transfer of anion resin has had no effect on anion leakage. However, it can be expected that sulfate leakage will increase as the resins age in service. For this reason, attempts are being made to modify the existing plant to minimize turbulence and to transfer the cation resin from the bottom of the separation vessel to the cation regeneration vessel.

The results obtained with TRIOBED are significantly better than those obtained previously. The leakage results to date are as follows:

Sodium - always below 0.1 ppb, and usually in the range of 0.01 to 0.06 ppb;

Chloride - always below 0.1 ppb

Sulfate - below 0.1 to 0.3 ppb

It is also noteworthy that theoretical conductivity is reached only ten minutes after a TRIOBED is put into service. The above leakage levels are reached only 20 minutes after starting the run.

b. NH_4/OH cycle

In conversion to the NH_4/OH cycle, the anion exchanger was first treated with 400 g/l (25 lbs/ft^3) of H_2SO_4 to remove re-

sidual chloride, then regenerated with 400 g/l (25 lbs/ft^3) of NaOH at 6%, then ammoniated with 0.5% NH_3 until the effluent sodium level fell below 1 ppm. The resin was rinsed to a conductivity of less than 20 micromhos/cm.

Significantly, for this test work, the condensate pH was increased to 9.3 to 9.4. During the initial test period, effluent sodium values were below 2 ppb. During a cycle which lasted seven days, very high condenser leakage was experienced during which the condensate contained several ppm of sodium. Even under these adverse conditions, effluent sodium remained below 3 ppb until the end of the cycle.

Chloride leakage remained below 0.5 ppb at all times, even with high levels of condenser leakage. The advantage of the anion sulfate treatment was therefore demonstrated. Sulfate leakage also remained low during NH_4/OH operation (0.2 to 0.6 ppb).

In another cycle, with no major condenser leaks and with a two-week run, similar results were obtained. The tests at Fawley are continuing and full results will be published by the CEGB in due course.

ACKNOWLEDGEMENTS

Ion exchange resins in water treatment

Dr L. de Lange

The use of ion exchange resins have become accepted practice worldwide whenever water with a high degree of purity is needed or whenever the water has to be cleared of dissolved impurities. In South Africa large volumes of water are treated daily with ion exchange resins, either to purify the feed waters for industrial boilers, or to keep the level of dissolved pollutants in the effluent at acceptable levels.

Modern ion exchangers are synthetic resins with a bead of granular-like appearance 0,3 to 1,2 mm in diameter. Its macromolecular polymeric matrix is functionalised with sulphonic or carboxylic radicals in the case of cation exchangers or amines in the case of anion exchangers. Not only is each individual resin particle porous and permeable to liquids, but the total resin bed, which may consist of a number of cubic meters of resin, allows dissolved salts to come into contact with the functionalities of the resin, as it perculates through the resin bed. This enables the functional groups to fix the cations or anions in solution. The fixation process is reversable, for subsequently the H^+ ions from an acid or the OH^- ions from a base replace, in stoichiometric proportions, the ions which have been fixed by the resin. This operation is called regeneration and allows the resin to be re-used many times.

Ion exchange is the ideal process for selective removal of even low concentration of impurities in water which are ionised to a greater or lesser extent. The ion exchange plant will be placed after other processes which have made use of precipitation methods (employing lime, aluminium sulphate, ferric chloride, or other floculating agents) followed by filtration to remove the suspended solids.

Treatment of water with ion exchange resins concerns itself with:-

a) Softening of water: the replacement of the calcium and magnesium salts by non-scale forming sodium salts.

b) De-alkalization: the cations bonded to the carbonates and bicarbonates are fixed on a carboxylic exchanger and the freed CO_2 is deliminated in a degasifier.

c) Demineralization: various ionized minerals, cationic or anionic, and often of metallic origin, can be removed often on a fairly selective basis. Potentially hazardous ions such as flouirides, may also be removed wherever the level thereof is critical in the environment.

d) Removal of organic foulants: organics, such as phenols, are often part of the effluent of various industries. In the case of phenol, treatment of the water with chlorine for bacteriological reasons may give rise to the formation of cholorphenols, which worsen the pollution problem. Other organics, such as dyes from dye works, can also be removed, using ion exchange resins or specially developed adsorbent resins.

e) Removal of inorganic foulants: ion exchangers have proved to be extremely versatile to remove heavy metals from waste waters, systems have been developed, using highly specialised ion exchange resins to remove dangerous materials such as mercury from effluent.

Although ion exchange resins have been known and used for many decades in industry and processes such as demineralization and softening, there are demineralization and softening, there are continuously new developments in improving the efficiency of the process and the quality and potential of the resins.

a. The Sirotherm Process

The effluent from a conventional deionisation process, based on ion exchange resins, contains a larger quantity of mineral salts than is removed from the deionized water. Ion exchange resins have to be regularly regenerated by acids, or bases. Even the most modern processes (counter-current flow, stratified beds) allow at least 2,5 equivalents to pass into the effluent for everyone removed. It may thus be claimed that conventional ion exchangers result in considerable inorganic pollution, which is greater, the higher the salinity of the water to be treated. A new deionisation process, called the Sirotherm process, has been developed, using ion exchange resins which partially deionises the water without polluting it. This process uses very special ion exchange resins, which can be regenerated with hot water at 90 °C. The consumption of chemicals and hence the pollution released into the environment, is minimal because it is restricted to the amount required for pretreatment.

b. The Triobed Process

Certain modern industries such as nuclear power plants, require water of very high purity and some designers may specify 150 ppb chlorides and 100 ppb sodium entering the reactor with the water.

The standard method of obtaining very high quality water, is to pass it, possibly after a preliminary partial deionization treatment, through an ion exchange mixed bed consisting of a strong cation and strong anion resin. This mixed bed process presents a number of problems, which centres around the difficulties experienced with seperation of the resin as well as mixed regeneration during the regeneration cycle.

In the Triobed process one of the three components is an inert substance which posesses no ion exchange properties. The particle size distribution and bulk density of the inert matter are selected such that, once mixed with strong cation and strong anion resin beads of a given particle size and bulk density, the Triobed seperates clearly into three layers after a liquid flow has been passed through to expand it.

This new process has proved itself capable of considerably reducing the permanent leakage rates generally encountered with traditional mixed beds. It is therefore used whenever a conventional process produces permanent leakage or conductivity levels which are judged to be too high.

c. Absorbent Ion Exchange Resins

The mechanism of organic matter fixation comprises both ion exchange and adsorption, using Van der Waals-type bonds in the latter instance.

Often the resins do not possess any ionizable functionality through surface phenomena, much like activated carbon.

The resins must be used whenever water containing organic matter, is to be demineralised. An indication of whenever the system needs the protection of adsorbent resins, is when the organic matters concentration of the influent water to a strongly basic anion exchanger of type 1 reaches 4 mg/ℓ ($KMnO_2$), or 7 mg/ℓ in the case of a type 2 resin.

CONTINUOUS ION EXCHANGE SYSTEMS

NIMCIX

The NIMCIX continuous ion exchange process developed by the Council for Mineral Technology (MINTEK) in South Africa is based on the Cloete-Street patented bubblecap for multi-stage vertical fluid-bed ion exchange systems. Several NIMCIX installations have been installed in South Africa for uranium recovery but none so far in water or effluent treatment per se, except one at Welkom for incremental gold recovery from an effluent using carbon adsorption.

The basic components of a NIMCIX system are illustrated below along with a basic flow diagram for the successful ChemWes Ltd. installation at Stilfontein where two 4.85 m Ø adsorption columns with 12 stages have been installed for adsorption and two 3 m Ø elution columns with 8 stages each.

NIMCIX technology and experience is available through MINTEK or several licensed engineering contractors:

PORTER CIX SYSTEM

The Porter CIX system originally patented by Robert R. Porter of Salt Lake City, Utah, in 1975, has been installed at numerous uranium recovery plants including Rössing Uranium Ltd. and many of the in situ leaching operations in Texas. The Rössing plant employs two CIX trains to treat 80,000 m^3/day pregnant solution containing about 160

NIMCIX ION EXCHANGE CONTACTOR SYSTEM FROM MINTEK, SOUTH AFRICA

For three decades, the exciting possibilities of ion exchange as a continuous process have intrigued chemical engineers. Now, the National Institute for Metallurgy has a system that makes those possibilities a reality.

In its search for a continuous ion-exchange process (CIX) that could be applied to the hydrometallurgical extraction of metals from their minerals, NIM, as the Institute is known, took the work of Cloete and Streat at Imperial College as a starting point. An extensive research and development programme that involved NIM, the Extraction Metallurgy Division of the Atomic Energy Board, and the South African mineral industry has now resulted in the development of a commercially proved contactor.

The development of this NIMCIX contactor saw its first breakthrough in 1970, when a demonstration unit with a column diameter of 1,8 metres was constructed and successfully operated at NIM.

In 1972, a pilot plant that had a capacity of 100 litres per minute was commissioned at a South African gold mine for the recovery of uranium.

The following year, a commercial plant for the recovery of zinc from spent pickle liquors was put into operation. The plant had a capacity of 210 litres per minute.

In 1974 and 1975, a demonstration plant with a capacity of 1 500 litres per minute was designed and commissioned for the recovery of uranium. The plant operated very successfully under automatic control and full industrial conditions for many months.

In 1976, a 200-litre-per-minute plant was installed at a gold mine for the recovery of gold from waste solutions. The absorbent was activated carbon.

During the next two years, a large commercial plant with columns of 4,25 metres in diameter was designed and constructed for the recovery of uranium. The plant was commissioned successfully and is operating at designed capacity.

In 1978, a number of NIMCIX plants were designed for the recovery of uranium on a commercial scale.

The NIMCIX contactor is suitable for use with activated carbon and all commercially available ion-exchange resins.

hydrometallurgy

The unit operations of hydrometallurgical processes generally comprise four steps:

1 **leaching** in mechanically stirred or air-agitated vessels, or on dumps, or *in situ* underground,
2 **solid-liquid** separation by countercurrent decantation and/or filtration,
3 **concentration and purification** of the clarified leach liquor, and
4 **recovery** of the metal either as a metal or as a compound.

For example, the conventional hydrometallurgical recovery of uranium includes concentration of the filtered leach liquor by solvent extraction and precipitation of the uranium as ammonium diuranate. The extraction of copper involves leaching with sulphuric acid (mostly in dumps), and either cementation or solvent extraction followed finally by electrowinning.

The traditional processes have certain limitations.

a The feed solution to recovery plants must be well clarified. Where recovery by cementation is practised, final polishing filtration is required to eliminate colloidal constituents of the solution, which tend to coat the metal particles and thus inhibit the cementation reaction. In solvent extraction, suspended solids adsorb the solvent and entrain it into the raffinate. The higher the amount of solids, the bigger are the solvent losses. These losses, which represent a significant fraction of the operating costs of solvent-extraction plants, can amount to about one-third of the total operating costs for copper and uranium.

b The mixer – settler systems in solvent extraction are not satisfactory for the treatment of low-grade solutions; yet the long-term need for metallurgical development is in the processing of low-grade ores. One problem with the mixer – settler systems is that, because losses of the solvent are proportional to the volume of the solution, the cost of these losses is inversely proportional to the concentration of the solution. Moreover, the entrained solvent may represent a pollution problem. Also, the capacity of mixer – settler systems per unit volume of plant is low because of the difficulty in separating the organic phase from the aqueous phase. Large plants, large inventories, and thus high costs result.

c Very clear solutions can only be obtained if sophisticated and expensive solid – liquid separation plant is installed. The finer the grind required to liberate the metal values, the more expensive is the separation plant. In a conventional uranium plant, for example, the clarification and filtration steps account for a significant proportion of the overall operating costs.

nimcix development

NIM became aware of the inherent advantages of ion exchange over solvent extraction many years ago, and realized that the problems of ion exchange in hydrometallurgy were associated mainly with the fixed-bed equipment. NIM started developing improvements in the technology of ion-exchange engineering in 1968, and paid particular attention to the idea of continuous ion exchange.

Early work showed that the fluidized-bed system (as distinct from the fixed-bed system) offered the best prospects for the following reasons:

a its ability to treat solutions that contain suspended solids,
b potentially low losses of resin,
c simplicity of construction,
d potentially high efficiency in the recovery of metals.

NIM therefore undertook a major programme of research with the specific object of developing a practical commercial plant. This object was broken down into a number of distinct projects in two broad categories.

A Engineering

1 Design and development of inexpensive distribution trays that divide the ion-exchange column into stages.
2 Development of methods for the control of the resin inventory in those stages.
3 Perfection of a method for the control of the movement of the resin.
4 Development of methods for the achievement of a balanced resin inventory when the absorption and elution columns are linked.
5 Improvements to methods for washing the resin to prevent cross-contamination.

B Process Design

6 Development of standardized laboratory methods for the study of resin capacity, kinetics, and hydraulic properties.
7 Application of laboratory results to process design.
8 Analysis and optimization of plant-performance data by the use of computers.

▷ *A commercial NIMCIX plant for the recovery of uranium. The absorption columns are 4,25 metres in diameter.*

operating cycle

The NIMCIX contactor is operated, according to the Cloete and Streat principle of reverse flow, in such a way as to give an intermittent flow of resin countercurrent to the flow of solution. The operating cycle is completely automated and is divided into five basic periods.

1 **Forward flow**
During the period of forward flow (absorption), the pregnant solution flows up through the column and fluidizes the beds of resin contained in each stage.

2 **Settling**
During this short period, the flow of solution is shut off and the resin is allowed to settle, as can be seen in the diagram, onto the tray in each stage.

3 **Reverse flow**
During the reverse flow period, a fixed volume of solution is allowed to drain from the column to the transfer vessel (V). This causes a fixed volume of resin to be transferred between the stages and also out of the bottom stage. At the end of this period, the resin that has left the bottom stage is distributed between the conical section of the column, the pipe connecting the bottom of the column with the transfer vessel, and the transfer vessel itself.

4 **Delay**
A delay period is necessary to ensure that all the resin in the conical section of the column and the line from it to the transfer vessel is moved to the transfer vessel by circulating solution through the conical section of the column and the transfer vessel itself.

5 **Resin transfer**
During the resin-transfer period, the transfer vessel is isolated from the column, and the slug of resin in the transfer vessel is lifted to the top of the elution column (not shown in the diagrams) by hydraulic pressure. The resin-transfer period and the next forward-flow period start simultaneously, as is shown in diagram 6.

The relative time taken for each of the five periods is shown in diagram 6.

The NIMCIX contactor is equally suitable for continuous absorption and continuous elution. However, in certain circumstances, fixed-bed elution is preferable to continuous elution in combination with continuous absorption. An absorption cycle that is much longer than the elution cycle is an example of such a circumstance.

nimcix features

The NIMCIX contactor has many interesting features, the following being the most important.

1 It will treat solutions that contain suspended solids.
2 The residence times are equal for all the resin beads of standard column-grade ion-exchange resins.
3 The fluidized bed occupies the full volume of each stage despite changes in the density of the resin as it passes through the column.
4 The equipment and method of operation are simple.
5 The contactor can be successfully scaled up to large diameters.
6 Resin losses are low.
7 Capital costs are low.
8 Operating costs are low.
9 There are relatively few valves in the system.
10 Efficient and stable operation is achieved over a wide range of feed rates and concentrations.
11 The plant is highly automated.
12 Start-up and shut-down are effected with ease.
13 The efficiency of recovery is high.
14 The reliability of the plant is high.
15 The availability of the plant is high.

▽ *This large NIMCIX demonstration plant operated continuously for many months on the recovery of uranium.*

nimcix applications

Uranium

NIM staff have made a major contribution to the development programme of the Extraction Metallurgy Division of the Atomic Energy Board on the application of NIMCIX to the recovery of uranium. The following were key factors in this programme:

1 the willingness of the NUFCOR group of companies to finance the 2,5 m diameter NIMCIX demonstration plant erected and tested at the Blyvooruitzicht Gold Mine; and

2 the imaginative decision of Rand Mines Limited to incorporate countercurrent decantation (CCD) and NIMCIX in a plant for the treatment of reclaimed slimes-dam material at their Blyvooruitzicht uranium plant; the successful operation of this plant has shown that, for Witwatersrand acid-leach pulps, CCD is a viable alternative to filtration and that NIMCIX operating on unclarified solutions is a fully proved industrial process.

Gold

Activated carbon is a highly efficient scavenger of gold from cyanide solutions. The use of granular carbon in the NIMCIX contactor, as had been suggested by Anglo American Research Laboratories, and an elution technique that has been developed by them, has proved, on pilot-plant scale, to be a highly effective system for the recovery of gold from very dilute streams. These solutions include waste waters emanating from conventional cyanidation plants, liquors from dump leaching, and return waters from slimes dams. The pilot plant has been operating at a flow rate of 100 litres per minute.

Zinc

A successful process that incorporates the NIMCIX contactor has been developed for the recovery of zinc from spent pickle liquors. The conventional system of fixed-bed ion exchange was found to be economically unacceptable for this application for two reasons. Firstly, the high concentration of zinc in the feed demanded a large resin inventory, which is costly; and, secondly, difficulty was experienced in the removal of occluded iron from the resin. The NIMCIX contactor offered the solution to both problems.

Copper

Although selective organic reagents have proved successful for the recovery of copper from acid leach liquors, the limited capacity and high solvent losses of conventional solvent-extraction plants mean that the treatment of solutions containing less than about 1 gram of copper per litre is probably uneconomic. Resins are inherently better suited to the treatment of low-grade solutions, such as those obtained from dump leaching and *in situ* leaching than solvents are. The new copper-selective resins have tremendous potential for the recovery of copper by the NIMCIX contactor.

nimcix today process design licensing

NIMCIX today

The development of the NIMCIX contactor has reached a stage at which it is a completely viable engineering system. The laboratory techniques, pilot-plant design, and design models that have been developed enable NIM's engineers to proceed with complete confidence in applying the system to the commercial recovery of gold, uranium, copper, and zinc. Development work on the adaptation of the system to the treatment of dilute slimes (resin in pulp) continues. Further process development is aimed at the recovery of gold from cyanidation-plant streams and the improvement of selectivity in the recovery of copper.

Process design

Engineers at NIM and at the Extraction Metallurgy Division of the Atomic Energy Board can estimate what size of NIMCIX contactor is required for any application once the following information has been established:

1 the flow-rate and concentration of the feed solution,
2 the density and viscosity of the feed solution, and
3 the approximate concentration of any ions in the solution that might compete for absorption sites with the metal being recovered.

The detailed process design for a particular application is based on the results of a few simple laboratory tests on the feed solution. Given representative samples, NIM can conduct these tests, which are designed to provide the following information:

a the rate of absorption,
b the equilibrium isotherm between the concentration of metal ions in solution and their concentration on the absorbent,
c the rate of elution, and
d a full analysis of the feed solution.

Licensing

The NIMCIX system is patented in many countries. In the U.K. and U.S.A., the NIMCIX system falls under an umbrella patent (Cloete – Streat) the rights of which are held by the National Research and Development Council.

NIM is prepared to enter into licensed manufacturing agreements with design and construction companies or process-equipment manufacturers, and to assist licensees with design information and, if necessary, with commissioning of plants. Those requiring information about existing licensees or the terms of the licence agreements should write to

The National Institute for Metallurgy,
Private Bag X3015,
RANDBURG 2125,
SOUTH AFRICA.

. The NIMCIX contactor

Plate Perforations

Contrary to speculation that the perforations in the plates separating stages might be conical or some other nozzle shape, it was determined that the plate perforation holes are in fact parallel sided.

Plate Material

At Chemwes plates are made of 20mm PVC supported on large rectangular cross section hollow steel beams completely covered by fiberglass reinforced plastic.

At Blyvooruitsicht the original stage separaton plates were made from polypropylene sheet supported on steel pipes (3" ϕ schedule 80 pipe) encased in sealed PVC tubing.

At Blyvooruitsicht new elution columns have just been built and at Merriespruit the plate separators are made from redwood boards. Holes are drilled into each board using a special template. By installing the plates as boards they can be dismantled and changed if necessary as they can then be taken in and out of the columns through the manholes.

Equipment List *

WIM Contactor System

1	Pregnant Solution Head Tank 4m dia x 7 m high - open
2	Pregnant Solution Pumps 250mm disch. - RL & SS fitted (incl. Standby)
1	Contactor Column 9 stage, 4.8m dia x 13m high - open, with SS Separation Plates between stages, and resin screens
1	Barrens Resin Screen Assembly - SS 1.5mm open x 5 sqm W/RL Frame
1	Resin Transfer Pump SS wet end 100mm disch.
1	Transfer Vessel 3m dia x 3m high - 6 bar pressure with SS resin screens
1	Sump Pump Vertical SS Wet End - 100mm disch.

Connected hp=125/demand=60 hp /Resin Load 73 cu m

All Tanks and Vessels are spun fiberglass.

mg/l U_3O_8 to yield barrens of around 8-10 mg/l U_3O_8. The system is operated for optimum economics rather than optimum efficiency.

A major difference between NIMCIX and the Porter system is that the Porter CIX stages are constructed side by side whereas NIMCIX stages are stacked one on top of the other. The NIMCIX system is somewhat more elegant and space efficient which could be an advantage in cold climates where the system needs to be housed in a building, but the Porter system is probably more practical as individual stages can be isolated for maintenance. Also, the side-by-side Porter system presents a more complicated resin transfer challenge requiring pumps, eductors, and external piping which are avoided in the NIMCIX system. However, the Porter system allows more precise control of distribution of resin between stages.

The carbon columns employed for gold adsorption onto activated carbon are all variations of the original Porter ion exchange system. These use screens (internal) for solid-liquid separation to keep the resin in each CIX contactor as the solution flows down the CIX train by gravity. The Porter system employs an eductor system to advance resin (as a slurry) counter-current to the solution flow. In each stage, resin is fluidized by the upflow of solution through some form of distributor to prevent solution short circuiting.

Companies that have experience installing counter-current contacting systems of this sort (including carbon columns for gold recovery) include:

SELECTIVE ION EXCHANGE RESINS FOR METAL RECOVERY

by F. X. McGARVEY AND J. UNGAR

Presented at the Symposium on Ion Exchange and
Solvent Extraction in Mineral Processing
Randburg, Tvl., Rep. of So. Africa February 7, 1980

The development of ion exchange processes to assist in the recovery and refining of valuable metals is reviewed with particular attention to nickel, cobalt and copper. Several selective resins have been considered from the standpoint of their structure, including those useful for gold and silver recovery. Current practice with the resins will be dealt with and some of the economics discussed.

The occurrence of organic compounds with unusually high affinity for certain metals has been observed for many years. Certain shellfish have unusually high affinity for copper, mercury and other metals in the presence of large amounts of electrolyte. Classic examples also include hemin and chlorophyll which hold iron and magnesium very strongly. Some of these naturally occurring compounds hold metals so strongly that they are not easily regenerated from the structure without destruction of the chelating group. The ability to perform oxidation reduction reactions while in the complex structure permits these metals to be part of complex biological processes.

Early attempts to produce resins having such selective properties closely paralleled the structure and grouping of natural compounds. The development of a class of synthetic chelating compounds based on amino carboxylic structures resulted in the incorporation of several of these structures in conventional condensation and copolymer systems. These resins frequently have ion exchange properties as well as the capability to form chelation rings.

Some of these compounds which received early attention are summarized as follows (from Helffe-rich [1], and Samuelson [2]).

The following is a potassium selective resin based on the specific precipitation of potassium salts with dipicrylamine.

This compound shows the characteristic 8-member ring so common to chelating compounds.

Polycondensation compounds also form chelation units as shown for anthranilic acid condensed with phenols.

Several selective resins have been considered from the standpoint of their structure, including those useful for gold and silver recovery. Current practice with the resins will be dealt with and some of the economics discussed.

The occurrence of organic compounds with unusually high affinity for certain metals has been observed for many years. Certain shellfish have unusually high affinity for copper, mercury and other metals in the presence of large amounts of electrolyte. Classic examples also include hemin and chlorophyll which hold iron and magnesium very strongly. Some of these naturally occurring compounds hold metals so strongly that they are not easily regenerated from the structure without destruction of the chelating group. The ability to perform oxidation reduction reactions while in the complex structure permits these metals to be part of complex biological processes.

Early attempts to produce resins having such selective properties closely paralleled the structure and grouping of natural compounds. The development of a class of synthetic chelating compounds based on amino carboxylic structures resulted in the incorporation of several of these structures in conventional condensation and copolymer systems. These resins frequently have ion exchange properties as well as the capability to form chelation rings.

Some of these compounds which received early attention are summarized as follows (from Helfferich [1], and Samuelson [2]).

The following is a potassium selective resin based on the specific precipitation of potassium salts with dipicrylamine.

This compound shows the characteristic 8-member ring so common to chelating compounds.

Polycondensation compounds also form chelation units as shown for anthranilic acid condensed with phenols.

An important configuration includes those which contain amino acetic acid groups. These include anthranilic acid-diacetic acid, m-phenylene diglycine and m-phenylene diaminetetraacetic acid.

By far the most common of these resins has been based on styrene-divinylbenzene copolymers with iminodiacetic acid groups as the functional group. The structure is shown as follows:

This resin has properties similar to the ethylenediaminetetraacetic acid compound widely used in analytical work and for heat exchanger cleaning.

Selectivity series for this type of resin are summarized as follows:

$Cu^{++} \text{-->>} Fe^{++} > Ni^{++} > Co^{++} > Pb^{++} > Mn >> Ca^{++} >> Mg^{++} >> Na^{+}$

also

$Hg > Cu > Pb > Ni > Cd > Zn > Co > Mn > Ca > Mg > Ba > Sr >>> Na$

Small variations in structure can play a considerable role in the actual affinity of neighbors in the series. The possibility that a particular structure may have substantial influence on a particular cation should not be overlooked but the sharp geometrical relationship of some zeolites is not available for resinous structures. This is usually fortunate since very specific materials may not regenerate easily or in some cases may absorb irreversibly.

Noble metals have also been concentrated on a series of chelating resins prepared with sulfur groups as part of the complex[3]. The complex has a structure similar to the following:

or

where M is a noble metal.

These resins bind gold and platinum metals very selectively from acid solutions. These resins can take part in redox reactions thru their double bonds so that substantial capacities for gold have been measured due to the formation of metallic gold. Similarly weak ester groups, $-CO_2R$, can be used in resinous structures to adsorb gold, probably thru hydrolysis of the group[4].

The various resins mentioned have differing degrees of selectivity but none can be classed as specific for a particular element. The only organic resin which can be called truly specific is one based on a styrene-divinylbenzene copolymer prepared with N-methylglucamine[5]. The structural formula is as follows:

Calmon[6] has prepared an interesting grouping of the various specific structures that might be considered for selective and specific ion exchange materials. He mentions thiourea and β-diketone structures among others for copper, cobalt and nickel as well as dimethylglyoxime for nickel. While it is doubtful that copolymer structures can be made sufficiently flexible to accept geometrical requirements of some of these compounds, there are many structures available for selective and specific ion exchangers.

Some modifications of these materials can also be considered where selectivity is required. First, the complexing agents may be bound on exchangers so that the functional groups are available at the exchange site. Rare earth separations are performed on such substrates with strongly held cations, as for example copper used to develop the trivalent cation separation[7].

It is possible to precipitate insoluble salts into resin pores so that the precipitate can act as a selective media for the removal of certain cations, including lithium, from brines. This method uses a macroporous anion exchanger to hold lithium aluminum silicate in the pores. When properly prepared the system can be used as a selective zeolite for lithium[8].

RECOVERY PROCESSES

The application of selective ion exchange materials must be compared to the performance of conventional ion exchange materials. The need for these materials arises from the lack of capability in conventional materials.

Selective (Chelating) Resins vs. Carboxylics for Base Metals

Conventional carboxylic cation exchangers have substantial selectivity at pH values above 4 or 5 for copper, nickel and cobalt in the presence of large concentrations of monovalent cations. Other divalent cations such as calcium and magnesium do not have the high degree of selectivity found in conventional carboxylics for copper.

However, to use the selective-adsorptive potential of a carboxylic resin, when working with acid solutions, it would be necessary to first neutralize the influent to the ion exchange column, not a very practical procedure in many hydrometallurgical applications associated with mining.

Consequently, carboxylic resins, such as Ionac CC or Ionac CNN, can be useful for heavy metal removed from industrial wastes, and from industrial (or potable water supplies), particularly where relatively low concentrations of heavy metals (still undesirable from the health or pollution standpoint) are present.

The selective resins, such as Ionac SR-1 or Ionac SR-11, on the other hand are much more effective for base metal removal at lower pH values (below pH 3 or 4), and their affinity for base metals (copper, nickel, cobalt, zinc) is such, that removal is essentially complete (residuals below the detection limits of analytical procedures), even for higher influent concentrations. This is contrary to the carboxylics, which would allow some leakage under such conditions. The selective (chelating) resins are therefore more suitable in hydrometallurgical applications (for economical considerations), and in pollution problems where absolute removal of the heavy metal ions is desired.

Some tests were also run on the sodium form resins, and a typical set of loading curves for nickel is shown in Figure 1, illustrating the advantage of Ionac SR-1 over Ionac CC at lower pH values. As however the total capacity of the carboxylic resin is higher, total loading to saturation is higher on it. The curves for copper and cobalt were almost identical.

A typical set of leakage and breakthrough curves is shown in Figure 2, illustrating the more complete removal of the base metal by Ionac SR-1.

Stripping of both types of resins was effected with 2N hydrochloric acid, and this is illustrated in Figure 3. It will be noted that somewhat longer tailing effects occur with the carboxylic resin than with the selective one, although because of its higher total loading, the stripping solution contained more copper chloride than found for IONAC SR-1.

Economic Considerations

Economics are only one of the factors in the choice of selective versus carboxylic resins in such process considerations.

The first and most important aspect is the tolerable heavy metal leakage in the effluent at the working pH. The selective (chelating) resins show much lower leakage, especially at low pH, so that their lower total capacity may well be offset by this factor. The breakthrough capacity difference will also be affected by the prevailing pH.

It is of course true that the selective (chelating) resins are generally more expensive per unit than the carboxylics, and this factor must be weighed against the others listed above.

Finally, the practicality as well as the operating expense of pH adjustment must be considered. The following two calculations for copper recovery will illustrate the points involved.

Case 1

Copper removal required - concentration: 100 ppm and pH must be retained at 2
Volume to be treated - 10 million liters per day
Capacity of Ionac CC - converted sodium initially-
5% (65 grams per liter)
= 3.25 grams per liter resin
Capacity of Ionac SR-1 - converted sodium initially -
36% (25 grams per liter)
= 9 grams per liter

Resin Requirement

Copper per day = 0.1 (10×10^6) grams per day =
1×10^6 grams

Ionac CC

$$\frac{1 \times 10^6}{3.25} = 0.308 \times 10^6 \text{ liters resin per day}$$

Ionac SR-1

$$\frac{1 \times 10^6}{9} = 0.11 \times 10^6 \text{ liters resin per day}$$

The chemical requirements and the conditioning of each resin would be in proportion to their capacity for copper so that these costs would tend to balance. The leakage of copper at this low pH would be quite high so that the chelation resin would have the best recovery and should be used.

Case 2

Copper removal required - concentration: 100 ppm and pH - adjustable to 4.5-5
Volume to be treated - 10 million liters per day
Capacity of Ionac CC
62% (65)
= 40 grams copper per liter
Capacity of Ionac SR-1
88% (25)
= 22 grams copper per liter

Resin Requirement

Copper per day = 1×10^6 grams
Ionac CC

$$\frac{1 \times 10^6}{40} = 0.025 \times 10^6 \text{ liters}$$

$$= 2.5 \times 10^4 \text{ liters}$$

Ionac SR-1

$$\frac{1 \times 10^6}{22} = 0.045 \times 10^6 \text{ liters}$$

$$= 4.5 \times 10^4 \text{ liters}$$

As in the previous calculation, the chemical consumption would be proportional to the capacity and would be equal per kilogram of copper recovered. Here the difference in resin cost would be crucial and the carboxylic should be selected if a small amount of leakage, roughly 0.1-0.2 parts per million, can be tolerated.

Polyamine and Amide (Weak Base Anion) Resins for Base Metals

The complexing of heavy metals by organic polyamine compounds is a well-known textbook reaction. The early polyamine-condensate type weak base resins, such as Ionac A-260 and Ionac A-305, are known to complex copper and other ions, and have occasionally been used in processes involving copper complexes.

Today's ion exchange technology provides us with a variety of other polyamines and amides, based on matrices such as styrene-DVB, styrene-acrylic, acrylic-DVB, pyridinium-DVB, etc., which may well offer suitable characteristics for hydrometallurgical separation or concentration processes. So far, little if any, work has been done in this direction, but it should be considered for some interesting possibilities.

NOBLE METALS AND MERCURY

The conventional process for recovering or concentrating noble metals by ion exchange usually accounts for the gold-cyanide anion complex, and sometimes the aurichloride or platinochloride complexes, being taken up by strong base anion exchange resins. While this is certainly a viable and economical process widely used, there is no selectivity involved, and substantial interference is experienced from anionic complexes of base metals, such as copper, nickel, cobalt, etc.

A macroporous chelating resin, Ionac SR-3, has been developed, which is highly selective for precious metals such as gold and others of the platinum group from acid solutions, as well as for mercury and methyl-mercury compounds.

Base metals such as iron, copper, lead, etc. do not react at all with this resin and do not interfere with the selective process. The noble metals are very strongly attached to the resin, yet their recovery presents no difficulty.

For example, one microgram of gold dissolved in one liter of slightly acidified water was completely recovered with the aid of Ionac SR-3. Furthermore, even after adding hundreds of milligrams of nickel and copper to the solution, precious metal recovery was complete to the exclusion of the other metals

Ionac SR-3 also quantitatively collects methyl mercury and inorganic mercury compounds. Both forms are collected from solutions of pH 1-9.

Table I shows the typical full loading potential of this resin for the various metals:

Table I
Capacities of Ionac SR-3

Gold	150 g/l
Platinum	65 g/l
Palladium	58 g/l
Iridium	25 g/l
Mercury	150 g/l

This resin is currently being used on the commerical scale in recovering gold from waste effluents and rinse waters of acid goldplating solutions. It is also suggested for noble metal extraction from ores and wastes, the separation of noble from base metals, the recovery of spent catalysts, the concentration of very dilute solutions containing noble metals and the refining of noble metals.

In addition, Ionac SR-3 is applicable to the removal of mercury (and methyl-mercury) compounds in pollution control.

Suggested Use Procedures

For the start of laboratory and/or pilot plant tests, the following use procedures should be considered, and would then lead to optimizing the process for scale-up:

1. The pH of the solution coming into contact with the resin should preferably be adjusted to between 0.5 and 2.5.

2. Adsorption of noble metals or of mercury is carried out at room temperature using conventional ion exchange column techniques. Minimum bed depth should be 750 mm and the flow rate about 10-20 bed volumes per hour.

3. The recovery of the noble metals from the resin is possible in two ways:

3.1 Ignition — Slowly roasting the exhausted resin in air at 900-1000°C leaves the metal in a very pure metallic form.

3.2 Elution — Eluting immediately after adsorption with a 5% aqueous solution of thiourea to which 5 ml/liter of HCl has been added yields a solution from which the metal can be recovered by reduction. When elution is applied, the resin can be reused for many cycles.

4. The elution of the mercury can be also accomplished by treating the resin with 4% sodium sulfide at a level of 200 g Na_2S per liter of resin.

Following the elution, it is necessary to regenerate the resin by treatment with 10% hydrochloric acid at a level of 100 g HCl per liter of resin.

SUMMARY

Selective and chelating ion exchange materials represent a significant advance in technology to meet the substantial demands for environmental control and material conservation so important in our modern day. These materials also have properties extremely valuable for nuclear decontamination where the trace leakage frequently found with conventional materials can be reduced.

Much applications development remains to be done on the various potential uses, but it is obvious that the probability that selective resins can be used to recover valuable materials in mining operations has a bright future indeed.

ION EXCHANGE - LIQUID-FILLED MEMBRANES

Liquid-filled membrane technologies offer potential improvements in selectivity and efficiency of metal recovery from solutions. There are two main thrusts of these investigations:

1) Development of organic ion exchange reagents with greater selectivity.

2) Development of contacting devices allowing simultaneous adsorption of metals from solutions on one side of a membrane and elution into a concentrated eluate at the other.

SELECTIVE ION EXCHANGERS

Significant progress has been made, albeit still at the pure research level, at developing highly specific ion exchange compounds. One of the leaders in this research is:

DR. ABRAHAM WARSHAWSKY
Dept. of Organic Chemistry
The Weizman Institute of Science
76100 Rehovot, Israel
(08) 48-2242
Telex: 361900

WARSHAWSKY (1982) reviewed current trends in the synthesis of selective ion exchange polymers incorporating oxygen, nitrogen, phosphorus, and sulfur ligands. Chelating ion exchange polymers incorporating hydroximes, amino phenols, polyethyleneimines, selective anion exchange resins incorporating pseudocrown ethers, or isothiourea groups and polymeric crown ethers are discussed in detail. WARSHAWSKY discussed synthesis of forty-one different types of ion exchange active groups for improved selectivity. Some of these are illustrated below just to show the variety of compound types under development.

WARSHAWSKY (1984) described hydrometallurgical processes for the separation of platinum group metals in chloride media in which these metals form ion complexes of the form $[MCl_x\ (OH)_y\ (H_2O_2)_z]^{n-x-y}$ which demonstrates the powerful nature of these processes.

WARSHAWSKY, et al. (1984) described thermally regenerable polymeric crown ethers with emphasis on their synthesis and application in electrodialysis. His paper is inserted below, again to illustrate the nature of these cyclic compounds which have selective metal extraction properties. Clearly, synthesis of these compounds is well beyond the scope of this study, but it is the nature of the compounds from which will emerge much more powerful ion exchange processes that is important here.

Thermally regenerable polymeric crown ethers. II Synthesis and application in electrodialysis

A. WARSHAWSKY, Department of Organic Chemistry, I. RUBINSTEIN, Department of Applied Mathematics, and O. KEDEM, Department of Membrane Research, The Weizmann Institute of Science, Rehovot, Israel

Polymeric crown ethers are synthesised from chloromethylated styrene divinylbenzene copolymers (I), which are converted to polycatechol (II) or polybenzylamine (IV). Cyclisation with α, ω-dihaloethylglycols, leads to polymeric benzocrown series (III) or polymeric diazapseudo crown series (V). These polymers can bind alkali metal salts, and the complexation process is temperature-dependent. Through complexation of alkali salts, the polymeric crown ethers behave as anion exchangers, and thus fill the function of anion exchangers in the electrodialysis system, without causing water-splitting.

1. INTRODUCTION

Recently, we described the synthesis of thermally regenerable polymeric crown ethers, starting from chloromethylated styrene divinyl benzene copolymers by two alternative routes.

(1) Friedel Crafts alkylation on I by catechol to give II, followed by Williamson condensation with α, ω-glycol dihalide in *n*-butanol to yield III [3, 4] (see scheme 1).

(2) Conversion of I to poly(benzylamine) IV, by reaction with hexamethylenetetraamine, and acidic hydrolysis, followed by a disubstitution reaction on a α, ω-glycoldihalide to yield V [1] (see scheme 2).

Another approach to the synthesis of polymeric crown ethers involves the sulphonylation of polybenzylamine [5] by 4-chlorosulphonylbenzocrown ethers [6], yielding polymers VI as described in scheme 3.

The polymeric crown ethers described bound alkali metal salts in a fashion similar to parent crown ether macrocycles, based primarily on the matching of cycle and cation radii. The main advantage of the polymeric crown ethers is the thermal decomplexation process, which occurs within a narrow temperature range and which allows the regeneration of the polymer and the alkali metal salt.

Scheme 1.

Scheme 2.

Scheme 3.

The thermoregulated decomplexation of polymeric crown ether complexes is determined by the properties of the ligand: the polymer serves as a 'separation medium' allowing the partition between the ligand and the metal salt.

In this paper, we describe a rather unusual application of polymeric crown ethers, in which the crown ether serves as an anchoring group for the cation, and the resulting positively charged entity acts as an anion exchanger. As such, it can replace conventional anion exchange membranes (AX) in electrodialysis. Since AX membranes are responsible for water dissociation, which occurs in a thin layer of the AX membrane — a phenomenon known as water-splitting.

2. RESULTS

For the preliminary study reported here a benzo-crown ether bound to a hydrophobic chain [6] was incorporated into dense cellulose acetate (CA) membranes. When the mixture of CA and complex (ligand + CsBr) was solvent cast and evaporated to dryness, clear films were obtained. These proved to be non-ideal anion-exchange membranes, as expected.

Transport and polarisation tests were carried out in a four-compartment cell (Fig. 1), with the tested membrane in the middle. Carbon suspension electrodes (7) were used to avoid pH changes by the electrode reactions. The area of the membranes confining the electrode compartments (C-membrane at the cathode and normally, except where stated otherwise, A-membrane at the anode) was 28.3 cm^2, while the area of the tested membrane varied between 0.8 and 3.1 cm^2. No stirring was applied in compartments I and II, so that polarisation was limited by natural convection only, and due to the different membrane areas was much more pronounced at the examined membrane.

Fig. 1. Scheme of the cell: A - anode; C - cathode; AM and CM-membranes confining respectively the anode and cathode compartments; TM - tested membrane.

Current was determined as a function of the potential across the tested membrane, measured between a pair of Ag/AgCl electrodes inserted on both sides at a distance of 3.5 cm. The potential thus contains some of the IR drop in the solutions. The plot of I versus V shows a linear region at low voltage, a plateau of varying breadth, and then a further rise of current at higher voltage, reaching a slope similar to the initial one. The current in the flat region is the limiting current.

Following this characterisation, current was passed through the membrane for 1–2 hours, at two current densities: one in the low linear region, and the other above the limiting value. Salt concentrations and pH were measured at the start and end of this period. The coulombic efficiency, η, refers to desalting of compartment I for the tested A-membranes, and to desalting in II for the C-membrane which was checked in comparison. τ is the transport number of the counterion, calculated from the membrane potential measured between 0.01 and 0.1 solution. pH_0 is the initial value and $pH_f^{I,II}$ the final ones.

Table 1 shows the corresponding results with the cellulose acetate–crown ether complex (CAC) membranes.

Table 1.

Water-splitting and coulombic efficiency in CAC membranes.

Tested membrane	τ	I(mA)	i(mA/cm^2)	i^{lim}(mA/cm^2)	Δt(min)	pH_0	pH_f^{II}	pH_f^{I}	η(%)	Protective A
I	0.89	2.00	2.55	1.5	125	5.67	6.25	5.30	83	Heterogeneous
		0.70	0.89		180	5.95	5.67	6.06	89	A
II	0.83	2.00	2.55	2.2	120	6.40	6.22	6.10	90	Heterogeneous
		0.60	0.76		121	6.45	6.20	6.31	98	A
III	0.89	8.00	2.55	1.5	120	6.50	6.15	6.45	64	Heterogeneous
		1.50	0.48		120	7.25	6.10	6.20	68	A
IV	0.92	8.00	2.55	1.5	60	6.50	6.35	6.20	77	Heterogeneous
		1.50	0.48		180	6.50	6.30	6.88	98	A
V	0.89	8.00	2.55	1.6	60	6.62	6.10	6.22	90	Heterogeneous
		2.00	0.63		150	6.62	6.25	6.65	92	A

Electrolyte solution was 0.01N CsCl (initial concentration). The coulombic efficiency, η, refers to desalting of compartment I for the tested A-membranes and to that of compartment II for C-membranes. I stands for the total electric current in the cell τ, for the counterion transport number of the tested membrane, calculated from the membrane potential i-current density at the tested membrane. i^{lim}-limiting current density, determined from the 'plateau' of the voltage/current curve: pH_0 refers to the initial state of solution, $pH_f^{I,II}$ to the final state in the appropriate compartments after time Δt of passage of current. Protective A refers to the type of membrane confining the anode compartment.

These results show clearly that water-splitting is indeed determined by the character of the charged groups in the anion-exchange membrane. pH-changes obtained at strong polarisation near the complexing membranes were very small. The decrease in coulombic efficiency for removal of Cl^- ion is small, but still evident, and is not necessarily accounted for by OH^- transfer. It should be remembered that we are dealing with fixed charges which are not covalently bound, and it is possible that permselectivity decreases at high current density.

3. CONCLUSIONS

Crown ether membranes can act as anion exchange membranes by incorporation of an alkali salt. The inertness of such membranes in an electrodialysis system has been demonstrated. Polymeric crown ether membranes have the potential of eliminating the problem of water-splitting, commonly associated with conventional anion exchange membrane of the weak and strong base types.

IX CONTACTING SYSTEMS - LIQUID-FILLED MEMBRANES

There are two reasons that liquid-filled membrane extraction is of interest to the water treatment industry:

1) Highly selective ion exchange reagents are being developed, but many of these will be expensive. By impregnating an organic matrix with these reagents, it is hoped that losses will be minimized to make their use affordable.

2) If a liquid-filled membrane can be designed such that as the metal ions of interest are adsorbed on the side in contact with the feed solution and simultaneous elution of the adsorbed metals to an eluting solution on the other side of the membrane, then the equilibrium of the transfer process could be shifted to be highly favorable.

LIQUID MEMBRANES

CAHN, et al. (1981) described the application of liquid membranes to copper recovery, specifically summarizing the results of development work carried out by DAVY McKEE R&D in Stockton-on-Tees on behalf of the EXXON MINERALS COMPANY. In this innovative form of liquid membrane (LM), an emulsion of eluant solution within the organic phase is dispersed into the aqueous feed so that loading and elution (stripping) occurs simultaneously.

Whereas SX requires multi-stage countercurrent mixing and settling followed by a similar stripping plant, also multi-stage, LM requires only multi-stage mixing followed by one settler to achieve the combined loading and elution. The result is a saving in equipment cost and cost of the organic inventory. Additional emulsion making and breaking equipment is required in LM.

The LM emulsion globules, typically 0.5 mm in diameter, are dispersed in the feed solution. There are many thousands of droplets of the strip solution within organic phase globules and the, of course, are very much smaller than the emulsion globules.

Copper transfers across the organic phase into the internal phase, and the organic phase thereby behaves like a membrane. The efficiency of extraction is similar to that of SX, and the resulting internal phase is suitable for feeding to a copper electrolytic tankhouse following emulsion breaking.

The organic membrane (that part of the globule separating feed liquor and microglobules of eluant) consists of three comonents:

- A chelating agent for copper extraction as in SX.
- A diluent or carrier solvent as in SX.
- A surface active agent to stabilize the emulsion which is not found in SX.

The diluent is often a mixture of solvents with a specific viscosity to assist in emulsion stabilization.

In addition to copper transfer, osmosis also occurs, and water transfers across the liquid membrane. This leads to internal phase dilution or emulsion swell. Some emulsion breaking occurs, and the internal phase leakage results in a net acid loss from the electrolyte (eluant). Both the emulsion composition and contacting equipment must, therefore, be designed to minimize swell and leakage.

In continuous test runs using real leach liquors, the emulsion was made up continuously. In full-scale operation, the emulsion would be made in conventional high shear emulsion making equipment which has demonstrated by both Davy McKee and Exxon. Contact

between organic and feed solution was in four mixer boxes in series, each with a residence time of 2½ minutes. A conventional gravity settler was used and provided the correct method of dispersed phase entry to the settler is used, no problems occurred. A novel new settler design of Davy McKee would likely be used for full-scale operations.

Emulsions are easily broken in an electrostatic coalescer, and this technique was used to continuously break emulsions in the test.

Steady state performance of the equipment and the membrane system was experienced over nine days of continuous operation. The same batch of membrane phase was used throughout. Extractions of 92-94% were achieved readily and to achieve 95% recovery, a slight increase in mixer box size or the addition of a mixer box would be implemented.

Osmotic swell was about 10%, which increased the volume of electrolyte and diluted its acid content. The increased volume must be compensated for by a bleed of spent electrolyte. Losses of the "internal phase" was between 1-2% and in this case, was calculated to add 0.5¢/lb. of copper for each 1% leakage.

The test program indicated where crud would accumulate and how much would have to be catered for.

The liquid membrane system operated successfully on an aqueous feed containing 200 ppm solids is typical of CCD overflow without feed clarification or filtration, thereby eliminating a capital cost item.

Conditions of the continuous test were:

Feed: 2.5 g Cu/l
Internal: 30 g/l Cu, 150 g/l Acid
Throughput: 300 ml/min. aqueous; 150 ml/min. of Emulsion
Retention Time: 10 min. (4 Boxes)
Duration: 9 Days

Results of the continuous tests:

Osmotic Swell: 10% by Volume of Internal Phase
Breakage: About 1%
Selectivity Cu/Fe: 130 to 1

A capital cost savings of 30-40% over conventional SX was indicated by the test results.

Within the objectives of this investigation, the two main areas of interest are:

1) The test demonstrates an interesting and potentially useful effluent treatment process which may potentially be refined to work more economically selectively than resin IX for metal removal.

2) The organic loss of 1-2% is still too large for consideration in applying the super-selective but expensive new ion exchange reagents being developed--however, if combined with super-efficient organics collecting techniques to recover them from treated effluent, this process may be developed for this purpose.

LIQUID-FILLED CARBON

D. Bhattacharyya has investigated the recovery/removal of metals in organic chelating agents adsorbed in carbon particles with a macroporous surface. EDTA, a chelating compound, and TRIANE, an organic sulfur-containing compund, were impregnated into carbon particules with 300 Å macropores. The carbon particles were then contacted with the feed solution. Once loaded, the carbon was recovered physically, and the metal values eluted by mixing them into an aqueous eluant at lower pH.

Although this mechanism is expected to result in a lower loss of organic phase due to its protection in the carbon macroporous housing, this process does not offer the advantage of simultaneous loading and elution (stripping).

It is not known how far the above development has advanced, but burther inquiries may be directed to:

LIQUID-FILLED MEMBRANES

New membrane materials have been developed which can be impregnated or coated with extremely thin films of the expensive but selective compounds. The concept is to use hollow filaments or film-type membranes which allow transport of the feed solution on one side and a continuous flow of eluant (stripping solution) on the other.

There has been some progress in this direction, but the companies and researchers involved are, for the most part, not yet prepared to discuss their results.

BEND RESEARCH

Bend Research has spent several years testing and developing liquid-filled plastic membranes.

BEND RESEARCH
64550 Research Road
Bend, OR 97701
(503) 382-4100
Dave Kamperman
Manager of Metal Separation
Harold K. Lonsdale
President

Bend Research is associated with a new company called Concept, Inc. that will fabricate products as needed. Bend Research undertakes R&D only. They have undertaken test programs to extract uranium and copper from acid solutions using membrane films and filaments. The conclusion drawn from work carried out on government contract was that the kinetics of film diffusion (the controlling factor for dilute solutions) made this type of recovery system too slow to be practical using the types of membrane configurations tested.

Bend Research, however, successfully demonstrated a practical recovery process for the recovery of metal ions from more concentrated solutions; for example, hexavalent chromium from metal finishing plant effluents. They developed a patented hollow filament 0.025 inch of i/d applying their liquid membrane technology. The walls of the membrane are filled with IX reagent. The Cr^{VI}-bearing effluent solution is transported through the inside of the tube, and Cr^{VI} migrates to the outside and is eluted continuously to the eluant in the surrounding space. This configuration was found to eliminate concentration

polarization problems. High flow rates are achieved through the length of the tube, and a high Cr^{VI} flux is achieved through the walls of the membrane. The modules are similar in appearance to R.O. module shell and tube design measuring 4"-6" Φ by 3' long. The concept is to recover Cr from more concentrated metal finishing rinse solutions before it is diluted while there is a smaller volume at several hundred mg/l Cr^{VI}. The process reduces the Cr^{VI} level to below 30 mg/l Cr^{VI}.

According to Bend Research, crown ether-type extractants may be very selective, but so far they result in low flux rates, especially for low-concentration feed solutions.

The comments of a company with several years of experience in trying to develop liquid-filled membrane systems appear to be relevent in alerting sponsors to what appears to be the big challenge in treating low-level solutions--namely, how to increase the surface area or the kinetics of film diffusion transfer.

WEIZMAN INSTITUTE, ISRAEL

Working closely with the reagent development experts mentioned above (Dr. A. Warshawsky's group), the Dept. of Membrane Research is developing membranes for application of powerful new reagents to metal recovery processes. This work is supervised by Dr. Ora Kedem who is certainly one of the most experienced and talented in this field.

Introduction

The liquid membrane separation process was first patented in 1968 for separating hydrocarbons.[1-4] This stimulated many researchers to join in the area of separating organic compounds.[5-11] Since then, its applications have been extended to the removal of contaminants from waste water,[12-33] encapsulation of enzymes and/or microorganisms for reaction and/or separation,[24-28] oxygenation of blood (artificial lung),[19] removal of toxins from blood (artificial kidney)[26,20] and metal extraction.[31-63]

This paper discusses the possible process schemes for using liquid membranes to separate and concentrate copper ion from its acidic leaching solution.

Analogy to a Conventional Liquid Ion Exchange Process

In a conventional liquid ion exchange process, there exists three distinct phases: an aqueous phase as the source of metal ion; an organic phase consisting of an ion exchanger dispersed in an organic solvent; and an aqueous phase as the sink for recovering metal ion from the organic phase. The process of recovering metal ion is accomplished in two consecutive steps. In the first extraction step, the metal ion in the source aqueous phase reacts with the ion exchanger in the organic phase to form a metal complex. The metal complex is soluble in the solvent but not in the aqueous phase. The organic phase, which now contains the metal complex, is referred to as the loaded organic. In the subsequent stripping step, the metal ion is stripped from the metal complex in the loaded organic and recovered as an ion in the sink aqueous phase.

In the liquid membrane metal extraction (LMME) process, the sink aqueous phase is emulsified into the organic (membrane) phase which contains the ion exchanger, and the transfer of metal ion is accomplished in a single simultaneous extraction-stripping process. As in the copper extraction case, the extraction step from the source aqueous phase involves the chemical reaction:

$$Cu^{++}_{(aq)} + 2HR_{(org)} \rightarrow CuR_{2(org)} + 2H^{+}_{(aq)} \qquad (1)$$

where $HR_{(org)}$ is the ion exchanger dissolved in the organic phase and $CuR_{(org)}$ is the copper complex in the organic phase.

The intermediate step consists of the diffusion of $CuR_{2(org)}$ within the membrane phase from one side of the membrane to the other side of the membrane.

The stripping step involves transferring copper into the sink aqueous phase by the inverse of reaction (1)

$$CuR_{2(org)} + 2H^{+}_{(aq)} \rightarrow Cu^{++}_{(aq)} + 2HR_{(org)} \qquad (2)$$

The overall transport of Cu is illustrated in Figure 1.

Equations (1) and (2), and Figure 1 explicitly indicate that the transfer of copper from a source aqueous phase through a liquid membrane into a sink aqueous phase depends on the copper concentration gradient in the membrane phase. This gradient is a function of the square of the hydrogen ion concentration in the two aqueous phases, the copper concentrations in the aqueous phases and the equilibrium constant of the ion exchanger in the particular solvent at a given temperature.

Potential Advantages of a LMME Process Over a Conventional Liquid Ion Exchange Process

The potential advantages of a liquid membrane metal extraction process are that 1) the extraction and stripping of metal ion can be accomplished in a single-stage operation and 2) the ion exchange molecule can be repeatedly used in a multicycle transfer of metal ion between two sides of the membrane during the single-stage extraction. The working capacity of the ion exchange molecule is thus increased accordingly, resulting in the use of lower concentration and consequently, lower inventory and losses of this expensive material.

Application of LMME Process to Copper Extraction

In the application of the LMME process to copper recovery, the first step is to extract the copper ion from the external aqueous phase (in this case, mine water or leaching solution) and then store it in the internal aqueous phase (in this case, sulfuric acid). The ion selectivity is controlled by the use of an ion exchange reagent such as Henkel's LIX 64N® dispersed in the membrane phase.

There are two basic ways of subsequently recovering the copper from the dispersed internal aqueous phase as illustrated in Figure 2. In one, the extracted copper is recovered directly from the internal aqueous by breaking the emulsion into an organic phase and a copper-rich aqueous phase. The breaking of the emulsion can be accomplished by a mechanical means,[65] by electrical coalescence, or by the addition of an emulsion breaker,[68] which can be separated from the organic and aqueous phases, usually by distillation and can be reused. The aqueous phase, loaded with copper, goes to electrowinning; afterward, the lean electrolyte is re-emulsified with the organic and recycled to the extraction unit.

The second recovery process, which has the same sequence of events as conventional solvent extraction, does not involve breaking the emulsion. Instead, the copper is recovered in a separate reverse liquid membrane extraction step to transfer copper from the internal aqueous to a new external aqueous, namely lean electrolyte, which thus becomes loaded electrolyte. This step is referred to as re-extraction.

For presentation at the SME-AIME Annual Meeting
Dallas, Texas - February 14-18, 1982

The schemes involving the mechanical breaking of the used emulsion and re-extraction were the subjects of a joint study between Exxon and Kennecott, while the scheme involving coalescing the emulsion was studied jointly by Exxon and Davy-McKee. The latter is currently recommended over the other two for copper extraction. All the above-mentioned schemes, however, will be discussed in this paper.

Experimental

Materials Used in Experiments

The membrane oil used was a mixture of surfactant and solvent. The surfactant used was a polyamine with an average molecular weight of 1500. The solvents used were S100N, Isopar M, and LOPS, either singly or a mixture of S100N with either Isopar M or LOPS. All these solvents are basically isoparaffin hydrocarbons manufactured by Exxon Chemical Company. However, S100N is much heavier than the other two -- the specific gravity for S100N is 0.836, whereas that for Isopar M and LOPS is 0.791. The "carrier" or complexing agent for copper can be any of the commercially available ones as long as it is completely soluble in the membrane oil. LIX 64N was one of several used in this work. The feeds used were synthetic mine water, synthetic leaching solution, and real leaching solution. The copper concentrations in these feeds ranged from 0.2 to 2 g/liter with pH varied from 0.5 to 3.5. The internal and external stripping aqueous solutions were prepared with reagent-grade cooper sulfate and sulfuric acid.

Emulsion Preparation in Laboratory

Emulsions were made either by extensive mixing of oil with internal aqueous in a glass vessel or Waring blender, or by mixing oil with internal aqueous in a colloid mill.

To prepare emulsions in a colloid mill, the mixture of oil and internal aqueous was charged into a mill made by Grifford-Wood, Inc. A milling time of six minutes was used in all cases.

Results and Discussion

Maximum Copper Loading Capacity of an Emulsion

One of the major differences between conventional copper extraction and a liquid membrane process is that of the function of copper storage in the intermediate extractant. In the former process, the copper is stored in the organic phase as a complex of the ion exchange reagent. For example, in selective extraction of copper with LIX 64N, the LIX will react with copper to form a hydrophobic copper complex which will preferentially remain in the oil phase. The maximum copper extraction depends on the total LIX available and the equilibrium conditions established between the aqueous solution and the organic. In the LMME process, on the other hand, the membrane phase is merely a transfer vehicle, and the copper is stored mainly in the internal aqueous phase as an ion, with only a small portion of copper stored in the membrane phase as a copper complex. The amount of copper stored in the membrane phase depends on the equilibrium between the membrane and the internal aqueous. The loading capacity of the emulsion depends mainly on the acid content of the internal aqueous and on the volume of internal aqueous (or the internal aqueous to oil ratio of the emulsion).

For a direct comparison of the loading capacities of the two processes, three sets of experiments were run to compare the loading capacity of copper in kerosene containing 7.5% active LIX 64N vs loading capacity of copper in an emulsion containing 7.5% LIX 64N in the membrane oil.

In the tests, a given amount of organic consisting of LIX 64N in kerosene or emulsion was repeatedly contacted with an equal volume of fresh mine water. In each step, the raffinate was drained and fresh mine water was added. The experimental results are given in Figure 3, showing the trend in the stepwise decay of extraction for three cases.

In the case of LIX in the kerosene, the extraction efficiency decreases drastically after just two steps. The percent copper extracted decreases from 92.1% in the second step down to 56.78% in the third step. In six steps the loading is completed, and no further extraction takes place. The total loading capacity of copper per gram of active LIX 64N was found to be 0.068 g/g of LIX.

In the case of an emulsion containing low acid internal aqueous (20 g/l H_2SO_4), the total loading capacity for copper was 0.147 g/g of LIX. This is more than twice the loading achieved with LIX in kerosene.

In the third case, where an emulsion containing high acid in the internal aqueous (151 g/l H_2SO_4) was used, the copper extraction was much better. Figure 3 gives the results of 17 repeated cumulative loading tests using a high acid internal aqueous. The percent copper extracted in each of the first 13 steps is more than 90%. The extraction efficiency of copper from mine water decreases gradually as the H_2SO_4 in the internal aqueous phase decreases and the copper increases. In 17 steps, the total copper extracted per gram of active LIX is about 0.35 g, a value about five times as high as the run for LIX in kerosene. It is expected that extraction can be continued for many more steps beyond 17 steps. Thus, the total loading capacity would be much higher than 0.35 g.

The above results indicate that in terms of LIX utilization per unit weight of LIX, the loading capacity of an emulsion is much higher than that of kerosene solvent. The advantage of using emulsion over conventional solvent extraction can be illustrated as follows: refer to Figure 3. Suppose a cross flow scheme is used to extract copper from parallel streams of mine water with the assumption that the extraction efficiency must be better than 90% in each step. In

conventional solvent extraction, the same solvent stream can be employed for only two cross flow stages, while an emulsion achieves target recovery for as many as 13 cross flow stages.

In the emulsion process, the loading capacity for copper can be increased by increasing the volume fraction of internal aqueous and by increasing its acid content. However, LMME with the maximum acid content has its limitations. For example, where subsequent stripping is used to recover the copper out of the emulsion, the acid content in the internal aqueous has to meet the constraint of allowing reasonable stripping of copper. Usually a high acid content will inhibit the re-extraction of copper into an external acid phase. Also, there may be problems with unfavorable water transfer where very high acid concentrations are used, and the emulsion/leach liquor density differential may be jeopardized.

Internal Phase Acid Concentration

The effect of increasing internal phase stripping acid concentration on copper extraction is illustrated in Figure 4. The greater driving force of the higher acid content is seen to lead to an increase in the rate of extraction. Emulsion swell due to osmotic transfer of water into the highly acidic internal phase has, however, increased by approximately 30%. Very high acid concentrations are not, therefore, recommended unless the membrane formulation is modified to reduce the transfer rate of water.

Bench-Scale Evaluation of Flow Sheet for Copper Recovery from Mine Water

The emulsion has the advantage of a high loading capacity per unit weight of extractant used. To make use of this loading capacity in the extraction stage, a cross flow scheme was designed where the emulsion is contacted repeatedly with fresh mine water.

The following describes the evaluation of an integrated flow sheet which incorporates a cross flow extraction section, a stripping stage, and electrowinning. The basic assumptions in the flow sheet are that the mine water contains 0.5 g/l Cu, the spent electrolyte composition is 170 g/l H_2SO_4, and 30 g/l Cu, and the internal aqueous cycles between 30 and 50 g/l Cu, an optimal range needed to meet the extraction efficiency target and a reasonable copper recovery in stripping.

A detailed cross flow extraction stage utilizing the emulsion of the above internal aqueous was evaluated by using a series of response surface experiments.

The extraction experiments were carried out in a jacketed separatory funnel at 35°C. The emulsion-to-mine water ratio was kept at 1:4, while the ratio of oil to internal aqueous in the emulsion was kept at 2.

In each experiment, 40 g of emulsion and 160 g of mine water were charged into the separatory funnel. After the equilibrium temperature was established, the mixture was tumbled for three minutes at the rate of one turn per second. After the tumble mixing, the dispersion was allowed to settle and separate into two layers. Small aliquots of raffinate were collected for copper analysis. From the analysis of the spent mine water, the change in copper content of the internal aqueous, the total copper concentration after the extraction, and the percent copper extracted were calculated. It was assumed that the copper retained in the membrane phase is negligible compared with the total copper extracted.

The design and the results of the regression experiments are given in Tables 1 and 2. The data in Tables 1 and 2 were used for regression analysis, and the results of this analysis are summarized in Figures 5, 6, and 7.

Figure 5 gives the contour of copper content in the internal aqueous after the mine water is extracted with a specified emulsion. Figure 6 gives the contour of percent coper extraction from the mine water when the mine water is extracted with a given emulsion. Figure 7 gives the contour of copper content remaining in the raffinate after the mine water is extracted with a given emulsion.

The construction of a flow sheet for the extraction of copper from mine water containing 0.5 g/l Cu can be resolved graphically as follows:

Suppose the mine water to be treated cross-flow with an emulsion containing 35 g/l Cu and 43.1 g/l H_2SO_4 in the internal aqueous at a ratio of emulsion to mine water of 0.25 in each contacting stage, and suppose the criterion of the extraction is to be that either more than 85% extraction is necessary or less than 100 ppm Cu (0.1 g/l) should remain in the raffinate so that it can be recycled after one contact. If the extraction is less than 85%, or if the spent mine water contains more than 100 ppm Cu, then the mine water requires a second extraction stage. The stepwise construction of the extraction flow sheet will be as follows: in the first step, an emulsion containing 35 g/l Cu is used to extract a mine water of 0.5 g/l Cu (point A1 in Figure 5); the copper content of the internal aqueous will rise to 40 g/l after the extraction (reading from contour in Figure 5). The extraction efficiency is better than 85% (point A1 in Figure 6). The copper remaining in raffinate is less than 100 ppm (point A1 in Figure 7). Thus, the raffinate can be recycled. In the next cross flow extraction stage, the above emulsion which now contains 41 g/l Cu is to be contacted with fresh mine water containing 0.5 g/l Cu (point A2 in Figure 5). After the extraction, the copper content will rise to 46.6 g/l Cu. The extraction efficiency is better than 85% (point A2 in Figure 6) and the copper remaining is less than 100 ppm (point A2 in Figure 7). This raffinate thus can also be recycled. In the next cross flow extraction stage, the above emulsion which contains 46.6 g/l Cu is again contacted with fresh mine water of 0.5 g/l Cu (point A3 in Figure 5). After the extraction, the copper

content will rise to 52.4 g/l. The extraction efficiency is better than 85% and the copper remaining in the raffinate is less than 100 ppm, still suitable for recycle.

Since batch experiments in the laboratory showed that 88 to 96% extraction can be achieved in three minutes, a residence time of five to eight minutes will be required in the plant under continuous extraction conditions, if we assume that each cross flow contacting stage is provided with several mixing compartments in series.

The re-extraction experiments were carried out under the following assumptions: 1) the aqueous phase in the emulsion contains about 50 g/l Cu, 2) the loaded electrolyte (external aqueous from stripping) to electrowinning contains 40 g/l Cu, and the spent electrolyte (external aqueous fed to stripping) contains 30 g/l Cu.

Four experiments were conducted at 60°C to recover copper from an emulsion (2 oil/l internal aqueous) containing 50 g/l Cu and 20 g/l H_2SO_4. The two external aqueous phases fed to stripping had the following compositions: 30 g/l Cu, 170 g/l H_2SO_4, and 32.5 g/l Cu, 166.2 g/l H_2SO_4. The ratio of emulsion to external aqueous was 0.5. The results were as follows: the increases of copper content in the external aqueous were, respectively, 3 g/l, 2.4 g/l, 3.1 g/l, and 1.7 g/l (average 2.5 g/l).

The stripping experiments indicated that the arithmetic average of copper increment during the stripping was 2.5 g/l Cu per step.

Assuming that each step of stripping recovers the same amount of 2.5 g/l, then a complete flow sheet of cross flow can be constructed for the stripping section.

Effects of Copper Concentration Gradient in Re-Extraction of Copper from Loaded Emulsion

A series of experiments was conducted to evaluate the importance of a copper concentration gradient in stripping copper from a loaded emulsion. In the experiments, the sulfuric acid concentrations for internal aqueous and for external aqueous (i.e., electrolyte) were 20 g/l and 170 g/l, respectively. The levels of copper in the internal aqueous were between 30 g/l to 50 g/l with H_2SO_4 levels as shown in the extraction experiments (see Table 2). The stripping was carried out in a jacketed separatory funnel at 55°C. the emulsions were made with an oil to internal aqueous ratio of 2. the results of the tests are given in the following table:

Initial Copper Concentration Gradient Cu (Internal-External), g/l	Net Increase in Copper Cu External g/l
45	8.95
35	6.4
20	4.8

From the above results, one could conclude that the copper re-extraction, or stripping, rate appears to be highly dependent on the copper concentration gradient. The bigger the concentration difference, the faster the stripping. However, internal acid concentration, which varies inversely with the internal copper concentration, has an even greater effect on the copper concentration gradient in the membrane, and it is this gradient which sets the stripping rate. This is further illustrated in the following section.

Stripping Experiments without Positive Copper Concentration Gradients

A number of re-extraction or stripping runs were made to show that stripping occurs even when there is little or no apparent copper concentration driving force in the outward direction. However, there was a sufficient difference in acid concentration between the internal and external phases to establish a copper concentration gradient in the membrane in the right direction to bring about the desired stripping action.

These experiments were batch with a 10-min. contact time, a 2:1 ratio of stripping liquor to emulsion, and a 1:1 aqueous/oil emulsion. All the experiments were conducted at 55°C.

Initial Internal Aqueous		Initial Stripping Liquor		% of Cu Stripped from Emulsion
Cu g/l	H_2SO_4 g/l	Cu g/l	H_2SO_4 g/l	
60	24	60	120	29
60	24	50	155	38
30	70	30	163	23
30	70	20	200	34

Note that in all cases the final copper concentration in the stripping liquor will be higher than the copper concentration of the aqueous phase in the emulsion.

Another observation is that stripping is a relatively slow phenomenon, as is to be expected because of the low copper concentration levels in the membrane phase when contacting both of these highly acidic aqueous solutions.

Continuous Stripping Experiments

A batch extraction time of 10 min. to remove about 30% of the contained copper from the emulsion translates to about 15 min. in a multi-compartment continuously-fed mixer. Continuous bench-scale stripping runs were carried out showing that 25 to 30% of the contained copper could be stripped out of an emulsion in 15 min. in a three-stage device. However, water balance becomes a problem since during this long contacting, the high acidic stripping liquor draws water out of a less acidic internal solution.

Conceptual Flow Sheet for the Re-Extraction Process

A conceptual flow sheet utilizing emulsion stripping rather than emulsion breaking can now be put together, based on mine water containing 0.5 g/l Cu. It is shown in Figure 8 with three cross-flow extraction stages operating at 35°C and four cross-flow stripping stages at 60°C. The emulsion circulating between these two sections swings between 35 and 50 g/l Cu. Stripping is done with the spent electrolyte containing 30 g/l of Cu, returning to the cell house with 40 g/l Cu.

Not shown, but certainly required, will be a small emulsion breaking facility to allow internal solution purge and adjustment and oil phase cleanup.

Equipment Design Studies

The equipment design variables examined are:

- Number and Size of Mixer Boxes
- Impeller Design and Speed
- Settler Design
- Method of Entry of the Dispersion into the Settler

Various types of impellers are being tested for use in the continuous equipment. The conclusions will prove valuable for impeller selection in larger scale plants. The interaction of impeller speed and emulsion type is also important. The effect of impeller speed on extraction efficiency in a continuously-fed four-compartment mixer is illustrated in Figure 9.

It may be seen that in this case there is no increase in extraction efficiency after 400 rpm has been reached and above this level, emulsion breaking and internal phase leakage increases rapidly (Figure 10). No effect on emulsion swell was observed. Selection of impeller type and speed is, therefore, as important here as in solvent extraction.

Emulsions were prepared successfully both with an impeller and with commercial equipment, such as a 10 gpm Tekmar Dispax DR 3-6/6. Depending on the membrane formulation and viscosity, emulsions sometimes needed to be recirculated through the emulsifier in order to reach uniform small droplets, such as $<1\ \mu m$.

The emulsions can be broken by several methods -- as noted previously, namely, by the commonly known electrostatic coalescence, or chemical methods, or a physical method which involves the use of centrifugation followed by high shear. The last method was tested with large-scale equipment. The centrifuges used were Sharples 6 in. bowl diameter Westfalia disc centrifuge. The high-shear device used was the Tekmar Dispax emulsifier. The centrifuges had no difficulty in handling the removal of the heavy emulsion which resulted when about 80% of the oil was separated. The heavy emulsion was then mixed with previously broken IR at 1 to 10 ratio (1 part of emulsion) in the Tekmar emulifier for inversion and thereby breaking. The results of demulsification sometimes could be improved by recycling the feed through the Tekmar emulsifier. The highest percent of IR recovery was 84%. Current design favors the use of an electrostatic coalescer because of its lower cost. A specially-designed coalescer gives excellent results of demulsification.[70]

Another equipment variable which requires special attention is the settler and the method of introducing the dispersed phase into the settler. The most important feature is that flow in the settler should be upflow so that the emulsion is carried to the under side of the settled emulsion phase. Complete and clean separation is then achieved and contact time between raffinate and emulsion in the settler which might lead to emulsion swell is minimized. The number and size of mixer boxes used in a continuous run will be discussed later.

Continuous Run using Freshly Prepared Pag. Leach Liquors

A continuous run was made at the laboratory of Davy-McKee to determine the long term effects of the constituents of real leach liquor on the LM system with membrane and internal phase recycle.

Fresh pregnant solution was prepared daily over a period of nine days. Freshly milled oxide ore was leached using sulfuric acid to an end pH of 2 under conditions previously determined in small scale tests. The suspended solids content of the feed was 200 ppm. At no time was the solution used more than 24 hr old.

The flow sheet used is shown in Figure 11. It has the following features:

a) Feed solution continuously fed to the extraction unit and raffinate recycled to ore washing.

b) Emulsion continuously broken and membrane phase recycled to emulsion making.

c) Electrowinning was simulated by adding acid and water to the recovered internal phase to simulate an electrowinning section spent electrolyte. A portion of this solution was then recycled to the emulsion making section.

d) Emulsion was continuously made.

Conditions of continuous operation are as follows:

Feed:	2.5 g/l Cu
Internal:	30 g/l Cu, 150 g/l Acid
Throughput:	300 ml/min. of Aqueous 150 ml/min. of Emulsion
Retention Time:	10 min. total (four boxes)
Duration:	9 days

Four mixer boxes in series each with a residence time of 2½ min. were used. A conventional gravity settler was used in the test. When the correct method of dispersed phase entry to the settler was adopted, as discussed previously, no problems occurred. The loaded emulsion was easily broken in an electrostatic coalescer.

Performance of the Membrane System in the Davy Continuous Run

Steady performance of the equipment and the membrane system was experienced over the nine days of continuous operation in Davy-McKee's laboratory. The same batch of membrane phase was used repeatedly, the only membrane added being the very small amount required to make up losses.

The extraction was between 92 and 94% throughout indicating that slightly longer contact time is probably required if over 95% recovery is to be attained. This may be achieved by increasing the size of each mixer box or by adding one more mixer box.

Osmotic swell of the emulsion internal is approximately 10%. Swell has the effect of increasing electrolyte volume and reducing the acid content of the electrolyte. The increased volume must, therefore, be removed in a bleed of spent electrolyte. The copper content of the bleed must be recovered, and this may be achieved using an electrolytic cell. Alternatively, the whole bleed may be passed to the leach section. In both cases, the acid content of the bleed will provide a part of the leach acid. When copper is not removed before recycling, however, the effect is to increase the quantity of copper circulating in the flow sheet, and it is therefore very important to achieve a high extraction efficiency if losses in the leaching operation are to be avoided.

Internal phase loss, or leakage, was between 1 and 2%. The significance of internal phase loss lies in loss of acid and consumption of tails neutralizing agent. Extraction efficiency is not greatly affected as the copper is rapidly reabsorbed. It has been estimated that internal phase losses add approximately 0.05¢/lb of copper for each 1% leakage.

In the continuous run, the ability of LM to operate successfully on an aqueous feed containing 200 ppm solids has been demonstrated. This level of solids is equivalent to that in the leaching section effluent and feed clarification may therefore be eliminated, reducing the capital cost.

Process Economics

The re-extraction LM process was compared with solvent extraction and cementation for recovery of copper from mine water. The investment for the LMME re-extraction process turned out to be intermediate between the low cost cementation and solvent extraction, a high investment process. Operating costs for the LMME process were somewhat lower than for the existing technology.

Subsequent comparison of the LM re-extraction process with LMME process alternates in which the emulsion is broken indicated a decided advantage for the latter. The whole stripping section with its four large mixer-settlers could be deleted, leading to a reduction in plant investment and solvent inventory. On the other hand, emulsion breaking facilities had to be increased to handle the full emulsion circulation, rather than just a purge stream. As the following table shows, the operating cost of the LMME process involving breaking the emulsion by centrifugation and high shear is about 20% cheaper than the solvent extraction process. A comparison of solvent extraction with the latest LMME process costs incorporating the emulsion breaking scheme is given in another publication[34] which shows a 40% reduction in investment for the liquid membrane process.

OPERATING COST INCLUDING 15% DCF RETURN

Solvent Entrainment in Raffinate ppm	Operating Cost: Conventional SX	Operating Cost: LMME ¢/lb Cu	Cementation: Scrap Cost $/ton	Cementation: Operating Cost ¢/lb Cu
0	25.7	20.5	—	—
30	27.1	21.8	—	—
90	28.2	22.7	—	—
190	33.2	27.0	—	—
—	—	—	80	26.7
—	—	—	100	29.7
—	—	—	100	31.2
—	—	—	120	32.7

Summary

The liquid membrane separation process is applicable in extracting and concentrating copper from its leaching solutions. Several process schemes were examined in this paper. The extraction part of all these process schemes is similar. The difference lies in how to treat the copper-loaded emulsion after the extraction step.

The emulsion can be broken to recover the internal copper-loaded phase by two effective physical methods — electrostatic coalescence and centrifugation followed by intensive shearing. In another scheme, the copper ion in the internal phase of the emulsion can be re-extracted out into an acid phase. In this method, the emulsion is regenerated without going through the demulsification and re-emulsification steps in a process.

In general, the re-extraction scheme should be used if the process requires a particularly stable emulsion, which is very difficult and costly to break; or where separation selectivity is insufficient with a simple permeation and re-extraction is needed to increase the enrichment. In the latter case, the re-extraction step

ought to be followed by demulsification in which a portion of the emulsion is broken to purge the accumulated impurities.

In comparison with solvent extraction, the liquid membrane process, in general, is cheaper. It requires less contacting stages, and the capacity of the liquid membrane emulsion for the material being extracted can be much higher than the capacity of the simple organic solution in a solvent extraction process. This is due to the presence of the encapsulated aqueous phase which acts as a storage reservoir. In addition, the concentration of the "carrier" or ion exchanger in the organic phase can be reduced, leading to lower inventory cost and potentially to lower organic losses.

For copper extraction, the liquid membrane process that utilizes electrostatic coalescing to break the emulsion is the presently recommended process over the other liquid membrane process schemes discussed.

ION FLOTATION

The Japanese in particular have conducted research into ion flotation. IZUMI, et al. (1976), for example, developed a process for foamy complex formation for removing and recovering heavy metal ions in dilute solutions with N-monodecanol diethylenetriamine. Heavy metals, i.e., Cu, Zn, Pb, Ni, Cd, Co, and Mn were removed and recovered from real and simulated waste waters by a foam-separating method using the organic reagent to extract the metals as foamy complexes that can be readily floated. The results are reported in a Japanese Journal in English.

MIYAMATSU, et al. (1983) studied the recovery of uranium from dilute uranium mine water solutions by fibrous anion exchangers. He found that the fibrous exchangers showed adsorptive capacities adequate for the recovery of U from solutions such as H_2SO_4 leach liquor, alkaline leach liquor, and mine water. Compared with conventional ion exchange resins, the fibrous anion exchanger demonstrated faster adsorption kinetics and better dispersion properties in solution. The adsorbent was stirred into the solution for best results. In an adsorption test using a two-stage counter-current system to recover U_3O_8 from an H_2SO_4 leach liquor containing 34.6 ppm U_3O_8, a repeatable 98% recovery of uranium and 60 fold concentration factor were obtained. Flotation was used to collect the fibrous adsorbent from the treated solution.

Celgard™ microporous polypropylene is now offered as hollow fibers as well as film. The fiber wall has properties similar to Celgard 2500 film. This hollow configuration may offer an advantage of higher surface area per unit volume in a separation device. Inside diameters are available in a range from 100-400 μ.

For further information, orders, or samples, please contact a Celgard representative at the address given below.

Cross-Section of Filaments (58X)

Diagonal Filament Cross-Section (90X)

Fiber Surface (8,000X)

Following are properties typical for 250-μ I.D. Celgard fibers. Most of these properties can be engineered to meet the requirements of specific end uses.

Properties of Celgard™ Microporous Hollow Fibers

Property	System	
Wall Thickness	0.98-1.18 mil	25-30 μ
Tensile Strength	7.8 oz/fil	220 g/fil

November 1980

Development of Waste Water Treatment at the Climax Mine

by Richard D. Gott and John M. Laferty, Jr.

Prepared for the
1977 American Mining Congress
San Francisco, California

Introduction

Since the 1930's Climax Molybdenum Company has operated a water recycle system utilizing active tailing dams and water storage facilities to collect mill water and return that water for reuse in the plant. This system allowed total containment of waste water, except during the annual spring snow melt period. The rapidly increasing runoff into the tailing system made it necessary to discharge some industrial water to keep the total system in balance. Annual discharge, occuring historically between April and June, averaged 2,400 acre feet per year and was bled into Ten Mile Stream at a controlled and monitored rate to maintain stream quality.

In addition to the recycle system, seep water pump facilities have long term been incorporated below each tailing dam at individual drainage areas to pick up all seep water for return into the tailing system.

Climax, desiring to go to a continuous discharge mode of operation, has been involved for the last four years in the development of technology to effectively treat plant waste water prior to any discharge from the Climax property. To implement this program, it was essential to define the drainage system surrounding the tailing impoundment area and effectively reduce this area with a series of interceptor canals to bypass as much runoff waters around the tailing system and into the natural streams. This series of interceptors then allowed for projections of the amount of runoff waters which could not be excluded from the tailing system and would amount to an inflow quantity of water which would have to be handled on an average annual basis to maintain total system integrity. Figure 1 graphically details the Climax tailing system with interceptors.

Climax outfall water contains small concentrations of heavy metals such as molybdenum, copper, and zinc in levels of a few parts per million. These metal constituents are the result of minor metal solubilization during the molybdenite flotation process. The mill water also contains combined cyanide in concentrations of less than one part per million. This is introduced into the mill circuit in the Regrind Plant as sodium cyanide where it is used as a copper depressant.

Laboratory work on removing impurities from Climax mill outfall water was started in 1973 with the removal of molybdenum from the mill water. This work led to the operation in 1975 of the Chem-Seps continuous Counter current ion exchange (CCIX) Pilot Unit. Through 1976, an intensive effort including pilot plant tests with the Swift Lectra Clear process has been underway to develop a system to remove the remaining heavy metals and cyanide. This paper discusses the process route selected to remove molybdenum, heavy metals, and cyanide.

Table I	Effluent and Feed Analysis						
	Fe	*Mn*	*Cu*	*Zn*	*Mo*	*Cd*	*CN*

Feed Ranges-mg/l	3.0-7.0	5.0-7.0	0.025-0.16	0.20-0.40	2.0-20.0	0.015	0.2-0.5

Laboratory and Pilot Plant Development

Laboratory and pilot plant programs directed at developing Climax waste water treatment technology were divided into two major efforts. Our first objective was to remove molybdenum to levels of 2.0 parts per million Our second effort focused on removal of heavy metals and cyanide. Target effluent concentrations for the heavy metals of interest and cyanide are listed in Table I along with typical influent concentration ranges of these same contaminants.

Development of a Molybdenum Ion Exchange Recovery System

The development of ion exchange technology for the removal of molybdenum to the low concentrations of 1-2 parts per million was started in mid-1973. The test work was restricted exclusively to the weak-base amine type anion exchange resin for two reasons: 1) the molybdenum absorption capacities were greater, and 2) the resin's high affinity for the hydroxyl ion allows for effective molybdenum elution with smaller alkaline requirements. Earlier column loading tests indicated that the amine type resins had a low capacity to absorb molybdenum when the resin was in the hydroxyl form but had a much greater capacity in the bisulfate or chloride form. Sulfuric acid was selected as the regenerant not only because of its lower cost, but also to avoid contamination of the effluent water with chloride ions.

Column Upflow Loading-Acidified Feed

Because of previous work done by AMAX[1] and others,[2] it was recognized that Mo sorption is most efficient at a pH between 3.0 and 4.0. Accordingly, the feed was acidified to pH 3.5 to 4.0 before entering the column. Amberlite XE-299 was selected after comparing loading capacity of the weak-base type resins available. With Amberlite XE-299, laboratory loadings of up to 12 pounds of Mo per cubic foot of resin at a cumulative percent recovery of 90.8 were obtained.

Resin Elution

Resin molybdenum elution efficiencies in excess of 98% were obtained. A typical elution curve is shown in Figure 2.

Paper presented at a Symposium jointly sponsored by the University of Reading and the Climax Molybdenum Company.

Figure 2

Ion Exchange Pilot Plant Operation

Chem-Seps Counter Current Ion Exchange Unit (CCIX)

The final phase in the molybdenum recovery program was to decide on an operating system to translate the laboratory procedure developed to a commercial plant. The CCIX unit was selected for piloting because, when compared to a fixed bed system, it requires considerably less resin inventory, it offers operating advantages at the high flow rates to be treated, and it occupies much less space.

The water processed in the CCIX unit was primarily Robinson Pond Tailing water. The Mo level in this water at the beginning of the test period was 11 parts per million. By the end of the period due to the dilution during the spring runoff the Mo concentration had dropped to 1 part per million. It was therefore decided to "spike" the feed with sodium molybdate to the level of 20 to 25 parts per million to facilitate the collection of the data required to design a full scale plant (resin loading, cycle time, elution efficiency, and resin degradation in operation).

The resin used was Rohm and Haas XE-299, a macroreticular weakly basic anion exchange resin, with tertiary amine functional groups. Sodium hydroxide and sulfuric acid were used exclusively for resin elution and regeneration at a concentration level of approximately 50 grams per liter. A photograph of the pilot CCIX unit is shown in Figure 3. Figures 4 and 5 describe the operation of the column in the service and pulse modes respectively.

Figure 3
CCIX PILOT PLANT UNIT
Tested at Climax, Colorado

The CCIX Unit is installed within a frame of structural steel tubing 5' x 5'6" x 27' high. The column is 31'6" total height. The pulse and load chambers are made of 304 stainless while the regenerate and elution sections are of tempered glass (later many were changed to PVC). The load chamber is 12" diameter. All others are 3" diameter.

Figure 4

Service Mode

The fully automated system operates by continuously cycling between a "service mode" and a "pulse mode." During a service mode, the loop valves A, B, C, D, and E are closed, effectively dividing the loop into five sections: loading, regeneration, elution, pulse, and resin storage. In the resin loading chamber feed water is pumped (Valve 1) downflow through the resin bed and treated effluent is delivered (Valve 2) from the bottom of the resin loading chamber.

Sulfuric acid regenerate at 50 grams per liter is pumped (Valve 3) through eluted resin in the regenerate section between loop Valves C and E and exits (Valve 4) as a barren regenerate after sorption by the resin of the bisulfate ion. Simultaneously, sodium hydroxide eluting solution at 50 grams per liter is pumped (Valve 6) through loaded resin in the elution section between loop Valves F and B and exits (Valve 7) as a sodium molybdate solution after desorption of the molybdenum on the resin by the hydroxyl ion.

Backwash water, which enters at the base of the reservoir vessel, fluidizes the loaded resin bed and carries foreign materials and resin fines out the resin overflow line.

Following backwashing, loaded resin from the resin storage area is gravity fed through loop Valve A into the pulse section. Sonic pulse control sensors close Valve A when the pulsing section is properly filled.

Figure 5

Pulse Mode

During the pulse mode, loop Valve A is closed and loop Valve B, C, D, and E are open. Valves 1, 2, 3, 4, 5, 6, 7, 8, 9, and 11 are closed. A hydraulic pulse of water (Valve 10) and a hydraulic secondary pulse of water (Valve 2a) transfer the resin around the loop for a preselected distance. This movement puts loaded resin from the pulse vessel into the elution section, moving stripped and rinsed resin from the elution section into the regenerate section into the loading chamber, and finally moving the loaded resin from the loading chamber aroun to the storage area. The pulse mode takes about 30 to 45 seconds. The unit then returns to the "service mode."

Evaluation of Pilot Plant Test Run

The test series demonstrated that an average Mo concentration of 2.0 parts per million could be obtained from feed concentration ranging from 2 to 24 parts per million. Average resin loadings were 3.66 pounds Mo per cubic foot of resin.

Molybdenum resin elution efficiencies in excess of 98% were obtained. Average eluate Mo concentrations ranged between 16 and 19 grams per liter.

At a downflow rate of 41 gallons per minute per square foot the pressure drop through the resin bed was 40 pounds per square inch. This was within the allowable maximum of 50 pounds per square inch as recommended by the resin manufacturer to avoid excessive physical resin degradation. No evidence of physical resin degradation was found during the pilot plant test period. A 20% resin loss per year has been established in laboratory test work.

Tabulated pilot plant test results are presented in Tables II, III, and IV.

Table II

Table III

Table IV

Heavy Metals Removal

As shown in Table I, the total amount of contaminant is quite small, however the difficulty of developing a viable process to remove that small quantity of contaminant is significant. After reviewing potentially applicable technologies, it was decided that five possible routes might yield workable processes for heavy metal removal. After running bench tests on all five options, it was clear that the only viable process was Swift's Lectro Clear system. The five technologies evaluated are reviewed below.

1. *Lime Precipitation:* Lime precipitation by itself was not successful as a potential solution due to the poor settling rates of the precipitated heavy metal hydroxides. Low water temperatures (0-4°C) and very low solids concentrations were responsible for the observed precipitate settling characteristics.
2. *Cation Exchange* — Column Loading Tests: Column loading tests showed that manganese, cadmium, and cyanide were not sorbed in any appreciable quantities.
3. *Sorption of Heavy Metals — MnO_2:* Column loading tests using a commercial grade pyrolusite (-6 +20M) as the absorbent was not effective because of early breakthrough of the heavy metals (250 gallons per cubic foot of sorbent).
4. *Ferric Hydroxide Sorption:* Increasing the amount of ferric-hydroxide via the addition of ferric sulfate prior to the lime precipitation step at a 8.6 pH showed no contribution to heavy metals or cyanide removal through physical sorption by the hydroxides, nor did it aid in solids settling.
5. *Swift Lectro Clear Process:* Positive bench scale tests and tests with a mobile trailer-mounted demonstration pilot unit at Climax during July, 1976 showed that the *Swift Lectro Clear* process held the most potential for meeting effluent requirements and thus should be tested further.

The Swift Lectro Clear process is a primary waste water treatment technique, designed to remove suspended material and/or hydroxide precipitates. After lime precipitate is conditioned in an electrocoagulation cell via contact with hydrogen and oxygen gases that are generated by electrolysis. The slurry is then mixed with a polymer flocculant and is floated in the electroflotation basin by "micro bubbles" of electrolytically generated oxygen and hydrogen and is subsequently skimmed off for disposal. The pilot unit was designed for an average flow of 10 gallons per minute and at this flow rate, residence times in the mobile unit were ten minutes in the neutralization tank, one minute in the electrocoagulation cell and 25 minutes in the electroflotation basin. Because of time limitations, the mobile pilot plant run used reagents in amounts necessary to produce a stable skim produce without attempting any optimization. Encouraging results of the preliminary trailer run led to a follow-up laboratory program to optimize reagent type and usage. During the laboratory testing program, a 10 gallon per minute pilot plant, Figure 6, was purchased from Swift and assembled in the No. 3 Mill Building at Climax. Laboratory findings were incorporated into a three month pilot plant program that culminated in an around-the-clock verification run. Table V presents performance results on the Lectro Clear system operation.

Table VI gives operating costs based on results from the continuous verification run.

Figure 6

Removal of Cyanide

There are currently many processes available for the detoxification of water cyanides. From a fundamental basis most of the commercially available methods utilize an oxidative approach to accomplish removal of both free cyanide and transition metal coordination cyanide complexes. A number of these processes have been evaluated in the context of Climax's needs and the results are summarized below.

Table V

PERFORMANCE OF LECTRO CLEAR PILOT PLANT PROCESS

Sample	Heavy Metals - mg/l						pH	CN	Turbidity

50 ppm Cl_2	0.04	---	0.02	-
Feed	0.18	0.18	0.18	0.18

Alkaline Chlorination

The alkaline chlorination process oxidizes cyanide by the addition of chlorine gas. The cyanide solution is first rendered alkaline (pH 10.5-11) and chlorine gas is injected into the process water stream. Laboratory test results, studying the effect of residence time, pH, and chlorine concentration are summarized in Table VII. Temperature was maintained at less than 10°C throughout all testing.

A confirmation test was carried out in our 10 gallons per minute Lectro Clear pilot plant at Climax. Chlorine gas was introduced directly after the lime precipitation step. Cyanide concentration was reduced from 0.14 parts per million to 0.07 parts per million with chlorine additions ranging from 5 to 50 parts per million. The low levels of 0.02 to 0.04 parts per million obtained in the lab were not reproducible in the pilot operation.

Table VIII

Laboratory Testing
Effect of Resident Time, pH, and NaOCl Concentration on CN Degradations

pH	8.8		10.6		11.6

Hypochlorite Treatment

Essentially the same reactions as in alkaline chlorination result from the addition of aqueous solutions of sodium or calcium hypochlorite. The use of sodium hypochlorite has been extensively studied in the lab as well as in the pilot plant at Climax. The use of calcium hypochlorite was evaluated in the lab and performed as well as sodium hypochlorite, however, economics dictate the use of the sodium form as it can be electrolytically generated from sodium chloride solutions.

Table VIII summarizes the laboratory tests utilizing NaOCl. Feed solution was fresh No. 3 Mill water and all tests were carried out at less than 10°C.

Based on the results of these tests, a continuous verification run, utilizing the most appropriate operating conditions and reagent addition levels, was executed. In

Table XI

PILOT PLANT RUN TO VERIFY FINAL PROCESS PERFORMANCE

Analysis	Heavy Metals milligrams per liter						pH	CN	Turbidity
Sample	Fe	Mn	Zn	Cu	Cd	Mo		mg/l	N/A
EPA permit Max. July 1977	2.0	1.0	0.2	0.05	0.015	2.0	6.0-8.5	0.025	N/A

[1]Effluent after Lectro Clear treatment for heavy metals removal

[2]Lectro Clear effluent after filtration

the pilot plant effort, the effect of pH, residence time, and NaOCl concentrations were studied. As is shown in Tables IX and X, the laboratory results were not reproduced in the Lectro Clear unit. The initial pilot plant cyanide test results were erratic with CN^- levels in the effluent varying between 0.04 and 0.08 parts per million. The average cyanide concentration in the effluent during the 66 hour run was 0.052 milligrams per liter. Also noted was that increasing the amount of hypochlorite addition did not materially affect cyanide degradation. Concentrations as high as 40 parts per million NaOCl resulted in no significant decrease in effluent cyanide levels as compared with 5 parts per million.

Although the laboratory results for cyanide degradation were not fully realized in the pilot plant circuit, the combined effects of cyanide removal in the ion exchange process and in the hypochlorite addition allowed the effluent to meet the cyanide limits.

Concurrent with the cyanide removal pilot plant testing it became evident that the heavy metal removal goals were not fully met with the Lectro Clear process. The problem centered on the requirement for a more complete elimination of precipitate. A decision was made to incorporate a high rate sand filter into the process scheme to "polish" or insure the quality of the effluent.

Tables XI and XII present a total circuit analysis including ion exchange, Lectro Clear process, oxidation, and sand filtering.

Table XII

PILOT PLANT RUN - OVERALL MATERIAL BALANCE*

Description	Fe	Mn	Zn	Cu	Mo	CN
Mass into System-grams	641	959	43	28	886	43
Removal by IX Column	---	3.1%	3.7%	11.6%	81%	71%

Removal by Filtration	15.1%	15.6%	10.7%	18.4%	-0-	0.9%
Leaving Filter to Pond	-0-	-0-	7.4%	6.8%	9.7%	5.6%
Removal by Total System	100%	100%	93.4%	93.7%	90.3%	96.4%

*Basis: 66 hours, 2.66% solids in skim, effluent pH = 10.5, feed pH to IX column 3.5.

Conclusion

Process definition for waste water treatment at Climax incorporates counter current ion exchange for molybdenum removal, followed by Swift electrocoagulation-electroflotation for heavy metals removal with a polishing filter for final effluent clarification. Sodium hypochlorite is added prior to the electroflotation basin as an oxidant for cyanide destruction. Pilot scale operations indicate essentially all the iron and manganese and in excess of 90% of the zinc, copper, molybdenum and cyanide are removed. The molybdenum removed by the ion exchange unit will be processed by solvent extraction-crystallization producing a marketable sodium molybdate. Skim electroflotation products will be chem fixed and returned to the tailing area for impoundment. The above processes are now being incorporated into a dual 2,000 gallon per minute plant with all pilot processes included in the production facilities. Full scale operation is planned in early 1978, to treat process water prior to that year's annual snowmelt.

The success of this process development is attributable to the cooperative effort between the Climax Mill, AMAX Extractive Research Group in Golden, and the AMAX Environmental Services Group, all providing specific expertise in outlining specific goals and objectives to this complex problem. The inclusion and adaptation of the Swift Lectro Clear process to treatment of process water at Climax is, we think, a first for the mineral industry and provides a novel and exciting approach to waste water treatment in the minerals industry for the future.

Mr. Richard D. Gott holds a BS in Mining and Metallurgical Engineering from the University of Idaho, School of Mines. He became Mill Superintendent at the Climax Colorado Mill in January, 1976. He chaired the AIME Intermountain Minerals Conference at Vail, Colorado.

Mr. John M. Laferty, Jr., is Manager, Extractive Metallurgy for AMAX Extractive Research & Development, Inc., at Golden, Colorado. Prior to 1974, he was with G.T.E. Sylvania as Manager, Chemical Research and Development in Towanda, Pennsylvania. He holds a B.S. Degree in Chemical Engineering from Villanova University.

In the development of this process, special thanks are due to Paul Zundel and Gary Van Riper of the Golden Lab and, also, to John Richards, Climax, Chief Metallurgist.

RESEARCH	Westinghouse Research & Development Center Pittsburgh, PA
CONTACT	Mike Skriva
TELEPHONE	(412) 256-5035
CAPACITY	Three CHEM-SEPS units treat 6,600 US gpm solution (1500 m^3/h) i.e. 2,200 US gpm each or 500 m^3/h. This is average flow rate. Loading section ϕ is 8 ft. Since the units pulse 45 seconds every six minutes, the flow rate during the 'Run' mode must be 8/7 x 2,200 US gpm = 2500 US gpm (545m^3/h). This is considerably less than was originally designed based on pilot plant work.
SPECIFIC FLOW RATE	Originally the units were designed for 55 US gpm/ft^2 2200 US gpm average flow rate corresponds to 44 US gpm/ft^2 specific flow rate. 2500 US gpm flow rate during 'RUN' mode corresponds to 50 US gpm/ft^2.
NOTE	Wyoming Minerals Corp is sensitive about information on the HIGGINS LOOP operation. The information provided here should be regarded as confidential even when talking to Wyoming Minerals' staff.

URANIUM GRADE	6-7 ppm U_3O_8 Grade may fluctuate to 5 ppm depending on the weather due to run-off dilution or depending on which tailings piles Kennecott Copper leaches that day. This corresponds with 6,600 US gpm flow rate for 365 days/year at 6.5 ppm head grade and 1.5 ppm barrens, i.e. 0.005 g/l extracted.
URANIUM PRODUCTION	140,000 lbs. U_3O_8/year
BARRENS	Used to be 1.7 ppm U_3O_8, now barrens of 0.9-1.2 ppm are experienced. The 1.7 ppm U_3O_8 average includes the third HIGGINS LOOP unit which doesn't run as well and gives higher barrens.
UNIT SIZE	8 ft.ϕ at loading section, the units are 55 ft. high. The three HIGGINS LOOPS fit into a remarkably small building.
LOADING STAGE	Originally the loading stages were 8 ft. high. Now loading stages have been reduced to 5 ft. height to reduce the pressure drop across the resin bed which was causing damage to the resin beads.
RESIN INVENTORY	750 ft.^{3} resin per unit (21.2m^3 each) Originally resin inventory was 1000 ft.^{3} (28.3m^3) prior to modification of the units.
RESIN TYPE	Macroreticular resin. Porous beads. DOWEX MSA 1 16-30 mesh (U.S. Std. Sieve)
RESIN COST	About \$125/ft.^{3} resin delivered \$4400/m^3 R 3500/m^3
RESIN SELECTION	DOWEX MSA1 was selected because it is both mechanically strong and resistant to osmotic shock. Ron Platzke claims losses are now such that the operation is economically viable. Gel type resins resulted in impossible resin losses to the extent that stable operation could not be achieved. DOWEX MSA1 has been used for the last 1½ years and has given a stable operation.
RESIN LOADING	1 to 2 g/l

RESIN LOSS

Resin loss in the CHEM-SEPS unit is high and is caused by:

-Osmotic Shock
-Mechanical Movement of the Resin
-Valves Closing on Resin
-High Pressure Drop Across the Resin Bed

Ron Platzke claims that resin loss is a result of valves closing on beads is low.

In the two years of their program with HIGGINS LOOPS to date Wyoming Minerals Corp. have used up about 12,000 ft.^{3} (340M^3) of resin in the three HIGGINS LOOPS WITH 750 ft.^{3} (21.2m^3) resin inventory each. This is roughly 270% per annum of resin inventory lost per year. A disastrous situation.

When Wyoming Minerals Corporation installed their first unit, the 1000 ft.^{3} resin inventory was destroyed within 6 hours. The unit had been started up under Chem-Seps supervision.

The resin inventory was replaced and it too broke in a day or so.

Then after performing some osmotic shock tests, the unit was filled with DOWEX MSA1 resin. This resin load lasted a week.

Each 1000 ft.^{3} resin load was worth $100,000, so in less than two weeks of running the unit, $300,000 worth of resin was destroyed. As a result, Wyoming Mineral's Corporation undertook a major resin test program, and modified the HIGGINS LOOP to downgrade its capacity thereby reducing the affects on resin loss.

Wyoming Minerals found that the resin breakage due to high osmotic shock and high mechanical shock applied t resin simultaneously was greater than the sum of the resin loss due to the two influences separately. In fact it was greater than the product of the resin losses from the two causes because the resin simply 'explodes'.

Mike Skriba of Westinghouse Research & Development has developed an RST (resin strength test) procedure and apparatus to measure resin losses on samples.

Resin losses now are believed to be around 100% PA of inventory or 54 PPM of flow rate of feed which is not bad at all.

Wyoming Minerals Corp. is actively searching for better resins and have developed a set of specifications which will enable resin to be manufactured for the HIGGINS LOOP that will last much better.

When comparing resin loss data for different CIX systems it is very misleading to compare on the basis of percent of resin inventory lost per year.

The HIGGINS LOOP treating 2200 US gpm has a resin inventory of only 750 ft.^{3} (21.2m^3).

NIMCIX at 1200 gpm requires a resin inventory of 5300 ft.^{3}. (150m^3).

Hence a 100% per year loss of resin inventory on a Chem-Seps unit at 2200 US gpm flow is equivalent to 5.3 PPM of flow.

5.3 PPM resin loss on a NIMCIX unit at 1200 gpm flow with 5300 ft.^{3} resin (150m^3) inventory would work out to 12.6m^3/year resin loss or 8.4% of the resin inventory.

It is therefore more appropriate to compare resin losses in terms of ppm of solution treated or volume of resin lost per unit of uranium produced.

Cost of resin loss per m^3 feed treated and per pound of U_3O_8 produced is compared below for 30%, 50% and 100% per year resin inventory losses on a Chem-Seps unit.

COST OF RESIN LOSS

21.2m^3 (750 ft.^{3}) Resin Inventory @ \$100/ft.^{3} per unit. Each unit produces 4.38mm m^3 x 5ppm x 2204.6 tbs = 48,280 lbs U_3O_8

At 30% Resin Loss Per Year

4.38 million m^3 solution treated per year per unit
= 6.36m^3 (225 ft.^{3}/yr) resin loss per year
= \$28,000 per year
= \$0.58 per lb U_3O_8 produced

At 50% Resin Loss Per Year

4.38 million m^3 solution treated per year per unit
10.6m^3 (375 ft.^{3}) resin loss per year per unit
= \$46,900 per year (\$125/ft^3)
= 0.97 per lb U_3O_8 produced

At 100% Resin Loss Per Year

4.38 million m^3 solution treated per year per unit
21.2m^3 (750 ft.^{3}) resin loss per year per unit

$94,000 per year cost of resin per unit ($125/ft^3)
$1.95 per lb U_3O_8 produced

RESIN DENSITY

The DOWEX MSA1 resin has an SG of 1.08 compared with SG = 1.1-1.2 for gel types. Resin density is not as important a feature for this type of contactor as for upflow systems.

FEED SOLUTION

Product of heap leached tailings dump rich in copper and high in particulates.
pH = 2.8 - 3.0 as received.

No resin poisons.

Very low SiO_2 content in feed.

ELUTION

Elute with three bed volumes of 150 g/l (3N)H_2SO_4
No copper gets carried over in the eluate.

ELUATE

300-500 PPM U_3O_8

TEMPERATURE

80°F or higher.

RUN/PULSE CYCLE

Resin is moved every 6 minutes. Each pulse lasts 10 to 15 seconds but the whole sequence including opening and closing valves takes 45 seconds.

SILICA

Very low SiO_2 buildup experienced--Less than 1% per year SiO_2 on the resin. pH is kept high enough to reduce the SiO_2 problem. At low pH's Ron Platzke believes that SiO_2 polymerises and "glues up."

RESIN REGENERATION

Not required at Bingham Canyon.

PARTICULATES

Suspended solids content of the feed solution at Bingham Canyon are high and vary considerably. Suspended solids of 1000 ppm are not uncommon. Variation depends on rainfall or snow melt runoff.

The particulates consist of flakelike particles of organics from the tincans used for precipitating copper cement.

In addition there are varying amounts of silt in the feed.

Particulates have a big impact on the HIGGNS LOOP operation. As particulates in the feed increase the pressure drop across the resin bed in the loading stages increases significantly.

Particulates also cause severe abrasion of pump.

PARTICULATE REMOVAL

Particulates are controlled as much as possible through three factors:

1. Installation of a one stage wooden settling tank ahead of the CIX unit.
2. Overflow solution is then filtered through sixty four ZURN strainers.
3. One section of the HIGGINS LOOP is used to backwash solids accummulated during the loading phase. The packed resin bed acts as a very good filter and will accumulate any solids present in the feed.

The HIGGINS LOOP is operated on a very short cycle of 6 minutes. The shorter the cycle, the less solids have a chance to build up in the loading stage between backwashes.

MAIN LOOP VALVES

21SSB Crane Monarch valves with squeegy disc wiper to reduce resin damage.

MAIN COST FACTORS

- Operators & Maintenance
- Resin Loss
- H_2SO_4 for Elution
- Na_2CO_3
- SX Chemicals
- Utilities e.g. Pumping Costs

MANPOWER REQUIRED

A total of 16 people plus three maintenance engineers are required to operate the plant.

5 foremen
6 process technicians
1 metallurgist
2 laboratory chemists
1 manager
1 clerk
16 Total

3 Maintenance Engineers

After Jacobs Constructors, who built the plant, left the site one of their crew left to go into business for himself and set up a small company that maintains the CIX units under contract.

OPERATIONAL AVAILABILITY

Now improved to 97-98%. Expected to drop to 90-98% as the new units get older and require more maintenance.

OPERATING SENSITIVITIES

All concerned emphasized that the HIGGINS LOOP is a very sensitive unit to operate.

When resin is pulse transported around the column in plug flow fashion it moves in what has been described as a "stick-slip" method. This leads to tremendous water hammer possibilities and enormous pressures seem to build up in the loop. Strain guage tests showed incredible forces in the column that could only be explained by resin bridging effects.

At times when resin blinds the collector screens drawing barrens from the loading stage of the loop, tremendous forces build up which bend the collectors which are very robustly constructed. Forces up to 1000 PSI on the collectors are experienced at times.

WMC SATISFACTION WITH HIGGINS LOOP

Mike Skrba at Westinghouse Research & Development Center, Pittsburgh indicated that the HIGGINS LOOP could be developed into the best system for continuous ion exchange in the world for cases where:

(1) Feed rate is very high
(2) Recoverable grade is very low
(3) Value of recovered material is high
(4) Sophisticated operators with prior experience running a HIGGINS LOOP are available.
(5) There is a space constraint for the plant.

RESIN REGENERATION

If resin regeneration is required then a means would have to be built into the system to do so.

The resin regeneration cycle would be different to other CIX systems.

The whole hoop might be taken off line temporarily and the whole resin inventory regenerated simultaneously.

MODIFICATIONS

Numerous modifications were made to the units at Bingham Canyon.

1. The LOAD section has been reduced in size from 8' to 5' to reduce pressure drop across the resin bed.

2. The ferric strip stage was removed. Ferric is now stripped from the resin in a different manner.

3. Flow rates to the units were cut back to 2200 US gpm average.

4. Several piping modifications have been made by Wyoming Minerals Corp on the units.

5. Wyoming Minerals Corp have modified the solution tenor control system.

CHEM SEPS CHROMIX SYSTEM

CHEM-SEPS CHROMIX PROCESS

Chem-Seps Chromix process provides a unique system for recovery of Chrome VI, Chrome III, and Zinc from cooling tower blowdown.

The use of the recovery system allows the preferred corrosion inhibitor chromates to be used and eliminates the pollution problems. The destruct system which is another alternative does not necessarily eliminate pollution. Chrome VI is reduced to Chrome III and precipitated. But today's EPA and other regulatory agencies requirement of 0.05 ppm total chrome are not achievable with the destruct system. Further the destruct systems are expensive to operate. A comparison of chemical consumptions between recovery and destruct is shown below.

	Recovery System	Destruct System
Sulfur Dioxide	None	2 lbs SO_2 /lb Cr^{+6} or 1 lb SO_2 /lb CrO_4
Sodium Hydroxide	0.75 lbs/lb CrO_4	2.5 lbs/lb Cr^{+6}
Sulfuric Acid	1.00 lbs/lb CrO_4	24.5 lb/lb Cro_4*

*This consumption is based on 20 ppm of CrO_4 and reduction of pH from 6.0 – 8.5 to 2. The reaction of reduction is best carried out at pH 2.

Typical System

A Chromix system to treat one million gallons per day (700 GPM) of blowdown with a Chromate concentration of 20 ppm would require one Chem-Seps Continuous Unit Model No. 5412 as shown in the flowsheet.

The cooling tower blowdown is pumped to the treatment section of the chromix system where the Chrome VI, Chrome III and Zinc are picked up on Chem-Seps special blend of ion exchange resins. The water leaving this section is essentially chromate-free and may be discharged. After the resin is loaded with the valuable corrosion inhibitors it is moved to the regeneration section. In the regeneration section Sulfuric Acid and Sodium Hydroxide are used to remove the Chrome VI, Chrome III, and Zinc from the resins. The sodium Chromate dichromate and Zinc Sulfate leaving this section may then be recycled to the cooling tower instead of going to sludge as in the destruct system.

OPERATING COST ECONOMIC ANALYSIS

Basis – Chromix System to treat one million gallons per day of cooling tower blowdown containing 20 ppm chromate. Unit model No. 5412 recovers 166 pounds of CrO_4 per day or 4,950 pounds per month. Capital Cost $200,000.

	Cost Per Month
Resin Replacement at $80 per Cu.Ft.	$ 350
Replacement Parts 3 percent of equipment cost	500
Chromate Make Up Cost 1 percent (50 pounds) at $1.75 per pound CrO_4	90
Chemicals and Utilities	
Sulfuric Acid	110
Caustic	180
Power	153
Estimated Labor Cost	
Operation at 1500 per month	1,000
Maintenance at 500 per month	500
TOTAL MONTHLY OPERATING COST	$2,883

Summary

Estimated value of chromate recycled equals $8,662.50 per month.

Payback on capital cost is estimated to be 2.9 years, plus installation cost.

Standard Continuous Units Fully Assembled

A full line of standardized continuous countercurrent ion exchange units have been designed to recycle chromates from 100 gpm up to 2000 gpm in a single unit. Each of these units are shipped fully assembled. A unit arrives on your site ready for feed and service piping connections plus power tie-in to the control panel. Installation and Start-Up cost are low.

Equipment Specifications Available

If you now operate a cooling tower and treat with chromates as corrosion inhibitors or if you do not presently use chromates but would prefer to use them, please contact Chem-Seps. Let us know blowdown rate and chromate level. You will receive a prompt reply including equipment specifications, operating data and an economic analysis that fits your specific cooling tower operation. It could be the start of improved, more economical, pollution-free cooling tower operation for you.

NITRATE REMOVAL FROM MUNICIPAL WELL WATER

JOHN C. GREGG, P.E.
SIDNEY B. BOWNE, JR., P.E.
PARTNERS
SIDNEY B. BOWNE & SON
MINEOLA, N.Y.

The Garden City Park Water District is located on Long Island in Nassau County, New York. Nassau is a Suburban County containing about 1,450,000 people in its 274 square miles and has fourty-four separate water purveyers within its bounderies. Long Island could most simply be described as a large sandbar separated from the mainland by salt water and the various water bearing formations underlying the Island and not geologically connected with the continental land mass. The result is that the only recharge available to these aquifers is that which comes from above in the form of precipitation, leaching from cesspools in unsewered areas, and storm water recharge basins.

Ground water quality has been closely watched for many years and after the rapid development of the area in the forties and fifties an increase was noted in the nitrate content. Not too much concern was paid to this increase except as a possible indicator of increasing pollution from cesspools, in fact at the time we were all concentrating on how to recharge the aquifers using effluent from sewage plants containing high concentrations of nitrates.

In the mid sixties references began appearing in literature indicating a probable correlation between the ingestion of water containing over 45 mg/l of nitrates by pregnant women in the last few months of their term, infants during their first few months, and the "blue baby syndrome". "Blue Babies" are actually suffering from methemoglobinemia, a serious and sometimes fatal disease caused by the nitrates interfering with the ability of the blood to carry oxygen to the tissues. Drinking water standards which limited nitrate as nitrogen to 10 mg/l were adopted by the U.S. Public Health Service and Nassau County.

In December of 1967, fully aware of the developing nitrate problem, the Garden City Park Water District received bids on No. 9 Well which was to be developed at the bottom of the deepest available aquifer at a depth of about 400 feet (122 m.). The double cased well was drilled by the reverse rotary method and the area between the outer casing and the soil wall was pressure grouted with a cement grout. After the customary one hundred hours of development and test pumping a complete chemical analysis was run which indicated a nitrate count of 1.8 mg/l. As all other items were also well below the prescribed limits we undertook the general construction, mechanical, electrical and site work and were ready for the final acceptance test in April of 1969.

After pumping the well to clear it, the final eight hour acceptance test was run at 1,200 gpm. (0.075 m^3/s). Samples for complete physical and chemical analysis were taken thirty minutes after the start of the test. Results of the chemical test indicated a nitrate level of 14 mg/l which later increased to as high as 22 mg/l. We had not then, and have not now, any satisfactory explanation for this increase. In any event, we ended up with a $300,000 installation which could not be used.

About this time in 1969 the Nassau County Department of Health analyzed 333 public supply wells for nitrate content and upon comparing the results with previous analyses determined that 24% of these wells showed rapidly accelerating rates of increase in nitrate content. In the case of Garden City Park, within a six month period, five of the older wells experienced rapid increases in nitrate content and three of them had to be removed from service. The District was faced with a 60% reduction of its 8,900 gpm (0.562 m^3/s).

Having no idea how to remove the nitrates, our first attempt at a solution was to backwash the well with system water which, by this time, contained about 6 mg/l nitrates. Our hope was to wash away or dilute any possible unknown concentration of nitrates in the area of the well screen or at least to dilute the groundwater in the screen area so that when withdrawn the nitrate concentration would be less than 10 mg/l. Over a period of several months we tried all kinds of combinations and permutations, but the results were consistently and conclusively negative. We were able to withdraw just about what we put into the ground for a net yield of zero. During this period we contacted and held discussions with various agencies and groups regarding purification processes used in other fields which might be adapted to solving our problem.

Investigation of various U. S. Department of the Interior programs for the removal of sulfuric acid and other wastes from various ordnance plant effluents disclosed interesting results from the use of an ion exchange process involving the use of "Continuous Countercurrent Ion Exchange" equipment which had been developed by Chemical Separations Corporation of Oak Ridge, Tennessee. In this process, Dowex synthetic ion exchange resins are used for the adsorption of contaminants. An installation which utilized tandem units to remove mineral impurities from strip mining water runoff was evaluated and we decided to process some Garden City Park water through a Chem-Seps pilot plant at Oak Ridge. Approximately ten thousand gallons (37.85 m^3) of water from Garden City Park and the Bethpage Water District, which was having similar problems, were trucked to Oak Ridge and processed through the Chem-Seps prototype plant. Analysis of the effluent by Chem-Seps, The Nassau County Department of Health and several independent laboratories confirmed that the process could reduce the nitrate content to well below the level required by the U.S.P.H.S. On the basis of these results, it was decided to design a plant for Garden City Park incorporating this ion exchange process.

The closed loop prototype unit consisted of 20 foot (6.1 meter) high loop of 3 inch (7.62 cm) diameter tubing and was operated in a batch mode at nominal pressure. Adapting this process to a continuous flow process at a rate of 1,200 gpm (0.075 m^3/s) at system pressures of approximately 80 psi (550 kPa) resulted in a loop approximately 32 feet (9.7 m) high containing a 24 inch (61 cm) diameter loop section for regenerating and rinsing of resin and a 72 inch (1.8 m) diameter section for treatment of the 1,200 gpm (0.075 m^3/s) flow.

The closed loop exchanger (Fig. 1) incorporates ion exchange "treatment", regeneration, rinse, and storage sections. A typical operation cycle consists of an initial pumping of a fresh charge of resin from the regenerant section to the ion exchange or "treatment" section. After adsorption of the nitrate ions, spent resin is pulsed into a resin regeneration section where it is regenerated by means of a brine solution. While the resin is being regenerated at one portion of the loop, high nitrate "raw water" is simultaneously flowing into the "treatment" or ion exchange section, being denitrated as it contacts the ion exchange resin, and flowing out. Resin is moved or "pulsed" around the loop about every ten minutes. The pulsing operation takes approximately thirty seconds during which time flow through the unit is momentarily diverted.

The ion exchange system cycles between a run mode and a pulse mode. During a 10 min. run mode, main valves at A, B, C are closed to make it a 3-section loop. Raw water is pumped into the contacting section through pipe 1 and flows down through the ion exchange resin bed; denitrated water flows out through pipe 2. Simultaneously, brine fed through pipe 4 into the regeneration section containing resin holding nitrate waste strips nitrate from the resin, and exits through valve 5 to the municipal sewage system. At the same time loaded resin drops through open valve D into the pulse section. Clear rinse water enters through valve 3 and washes brine traces from resin about to re-enter the "contacting" section of loop. The conductivity-sensitive controller regulates rinse until traces of brine are removed. This properly positions the interface for the next pulse.

During the 30-second pulse mode, main valve D is closed and valves A, B and C are opened. A timed pulse of raw water through valve 7 transfers loaded resin from the pulse section to the regeneration section, regenerated rinsed resin back into the contacting section, and loaded resin into the storage sections. Backwash water from valve 6 cleans resin fines and foreign particles from the loaded resin. Upon return to the run cycle, valves A, B and C close and valve D opens allowing resin to drop into the pulse section.

Fig. 1—Diagram of the ion exchange operation.

In other applications, untreated water is drawn from an unpressurized tank as needed, and the treated water pumped into an open receiving tank. The pulsing characteristic or stop-and-go operating cycle therefore does not pose problems.

Such start-and-stop operation could not be tolerated in the Garden City Park water system. Elevated storage tanks are about one mile distant, too far to allow economic, direct pumping of treated water. Water must be pumped directly into the system's mains which operate at 80 psi (550 kPa). Stop-and-go pumping would pose serious wear and short-life problems on the well pump, valves, and electrical equipment and cause additional problems from sonic and hydraulic harmonics, comparable to "water hammer".

The interrupted flow problem was solved by introducing a bypass system which would allow the well pump to operate continuously, maintaining proper water volume and pressure in the mains and distribution system.

The final system devised utilizes a bypass system of piping, automatic valving and a hydropneumatic tank. Start up of the plant is initiated by a drop in water level in elevated storage tanks, which signals the well pump to start. When the well goes on stream, it signals the ion exchanger to operate. After a preset period of pumping, solenoid valves shut down delivery of the raw, nitrate laden water from the well to the chamber, and divert it

automatically into a bypass water circuit which includes a 5,000 gal., (18.9 m^3) capacity hydropneumatic tank. Well water is diverted for 30 seconds directly to the hydropneumatic tank, mixing with the denitrated water pumped there earlier from the ion exchange chamber. The system is designed to operate continuously at 80 psi. (550 kPa). If pressure exceeds 100 psi (690 kPa) the entire system shuts itself off.

Automatic Nitrate Analysis – The Nassau County Health Department requires that the nitrate content be monitored. This is done by a Delta Scientific automatic nitrate analyzer which is set to shut the well pump and ion exchange system off should the nitrate content of the processed water rise to 5 ppm. It also shuts the system down on a zero reading caused by reagent or analyzer failure.

The on-line instrument originally had a sample-to-readout lag of 23 minutes as compared with a laboratory chemical analysis time of at least an hour. The 23 minutes lag between sample drawing readout would amount to 27,600 gallons (104.6m^3) of water at 1,200 gpm (0.075 m^3/s.) This time lag has since been reduced to 15 minutes at the recommendation of the Nassau County Department of Health.

The 33 ft. (9.5 m) tall exchange loop and associated equipment are hidden from view within a specially designed "ranch house", compatible with the residential community. The ranch house, of contemporary design, is 28 ft. (8.5 m) by 54 ft. (16.2 m). Its basement is large enough to permit equipment to be installed 18 ft. (5.4 m) below grade. The new plant is the latest in automatic, failsafe operation, with a remote alarm in the community's firehouse. Total cost of the housed system is about $425,000.00.

CHEM-SEPS CONTINUOUS ION-EXCHANGE CONTACTOR AND ITS APPLICATIONS TO DE-MINERALISATION PROCESSES

By I. R. HIGGINS and R. C. CHOPRA

(Chemical Separations Corporation, Oak Ridge, Tennessee 37830, U.S.A.)

The Chem-Seps continuous counter-current ion exchange contactor is described and its applications in both the water treatment and chemical process industries are given.

The principal application for the Chem-Seps single loop continuous system is in the de-mineralisation of water for boiler feed and other uses. Chemical efficiencies and therefore lower operating costs have been the principal reasons for installing Chem-Seps systems.

The 'down flow' system used by Chem-Seps overcomes many of the handicaps of continuous 'up flow' systems. There is no minimum flux requirement. Untreated water is used for pulsing. The process water requirements for complete de-mineralisation of water with a high content of solids (1800 ppm) are less than 10% of throughput. The 'down flow' configuration also keeps heavier liquids in the lower regions of the equipment allowing more efficient interface control and preventing channelling.

The resin inventory in Chem-Seps continuous counter-current ion exchange can be as low as 15% but rarely over 30% of the volumes required for conventional fixed-bed systems.

The Chem-Seps system can handle slurries effectively. The capability to handle slurries makes the regeneration of resin with low-cost lime practical. In Sul-biSul, the acid produced in regeneration step if neutralised with lime slurry reduced waste volume and higher utilisation of resin capacity. The increased efficiency of the system makes it worthy of consideration for de-mineralisation.

The waste volume in continuous counter-current ion exchange is normally 2·5–5% of throughput for waters with 400–1000 ppm total dissolved solids.

Addition of the 'down flow' design to the 'Higgins' on single loop system has enhanced its versatility as a process tool in both water and chemical process de-mineralisation applications.

Introduction

There are over 70 continuous counter-current ion-exchange units designed by Chem-Seps installed around the world de-mineralising, de-alkalising, and softening water and working on various other chemical process flowsheets. Predominantly, the larger installations are involved in the de-mineralisation of water for boiler feed and process water requirements. Partial de-mineralisation of brackish waters for potable uses is becoming increasingly important. De-alkalisation for process water for such applications as textile bleaching and softening for low-pressure boiler water would rank next in importance. There are a number of units used in the softening of potable water for municipal or private water districts. Examples of some of the other chemical process flowsheets are: magnesium removal from phosphoric acid to prevent after-precipitation in the production of 'super acid'; recovery and treatment of certain plating wastes for cost reduction and pollution control; extraction of uranium from ore pulp; de-mineralisation of thin sugar juice to increase yield and reduce scaling of heat exchanger; and many other special types of chemical process flowsheets.

The use of continuous ion exchange for de-mineralisation of water accounts for about 70% of the total use and will be emphasised in this paper. There are many variations possible in devising a de-mineralisation flowsheet. The final choice of flowsheet and the equipment to be used is dependent upon the characteristics of the untreated water, the quality requirements of the effluent, cost and the availability of regenerant. Most of the engineers and operators who have decided to install Chem-Seps continuous counter-current ion-exchange (CCIX) systems most frequently have based their decision on the savings in operating costs that are possible because of the characteristic counter-current flows in the Chem-Seps system, compared with conventional fixed-bed systems.

Chem-Seps system

Chem-Seps continuous counter-current ion-exchange is a loop in which various sections are separated by valves to separate the sections performing different functions simultaneously (see Fig. 1). The resin is moved in small increments by the hydraulic ram action. All solution flows are counter-current to the flow of resin. The contaminants are removed in the process cycle and the resin is moved in the pulse cycle. A controller in the effluent stream from the loading section senses the upper limit permissible in the effluent. In the process cycle, the influent enters through a set of distributors, moves downward and leaves through another set of distributors. Simultaneously the regenerant enters through valve K and leaves through valve E. The rinse enters through valve I and its duration is controlled by an interface controller.
